The above arguments seem to tell us that the consistency with the GR predictions—more formally, the GR limit—is a trivial problem. However, when the system of Eq. (1.3) is solved, the result may show a completely different story. In fact, it is very common that a general solution of Eq. (1.3) does not reproduce any GR space-time metric by simply setting $\alpha = 0$. The origin of this problem is in the non-linearity of the system (1.3), and it should not come as a surprise. To clarify this point, let us consider a static and spherically symmetric perfect fluid. The most general spherically symmetric space-time metric can be written as

$$\begin{aligned} ds^2 &= g_{\mu\nu}\, dx^\mu\, dx^\nu \\ &= e^{\nu(r)}\, dt^2 - e^{\lambda(r)}\, dr^2 - r^2 \left(d\theta^2 + \sin^2\theta\, d\phi^2\right)\ , \end{aligned} \tag{1.4}$$

where ν and λ are functions of the areal radius r only. The Einstein equations (1.1) then yield the metric component

$$e^{-\lambda} = 1 - \frac{2\, m(r)}{r}\ , \tag{1.5}$$

where

$$m = \frac{k^2}{2} \int_0^r \rho(x)\, x^2\, dx \tag{1.6}$$

is the (Misner-Sharp) mass function of the self-gravitating system. Now let us consider the same perfect fluid under the "new" gravitational theory defined in Eq. (1.2). When the Eq. (1.3) are solved we obtain an expression which may generically be written as

Fig. 1.1 MGD: the new gravitational sector not described by GR is fully controlled by the deformation parameter α. GR represents a "sub-space" in this extended version of gravity and is recovered for $\alpha = 0$

$$e^{-\lambda} = 1 - \frac{2\,m(r)}{r} + (\textit{geometric deformation})\ , \tag{1.7}$$

where the term *geometric deformation* should be understood as denoting the modification undergone by the metric component in Eq. (1.5) due to the generic extension of GR shown in Eq. (1.2). Therefore "deformation" means the difference with respect to a specific GR solution. Now, and this is very important, the deformation shown in the expression (1.7) always induces an *effective anisotropy* on the perfect isotropic fluid. Hence, the self-gravitating system does not behave like a perfect fluid anymore. Indeed, and this is a critical point in our analysis, the anisotropy $\mathcal{P}$ produced by the geometric deformation always appears to be of the form

$$\mathcal{P} = A + \alpha\, B\ . \tag{1.8}$$

This expression shows that the GR limit cannot be recovered simply by setting $\alpha = 0$, since the α-independent contribution A in the anisotropy (1.8) will survive in this limit. Consequently, the perfect fluid GR solution (1.5) is not contained in this extension and we could say that we have an extension to GR which does not contain GR. This seems a contradiction, but it is in fact mathematically correct and appears more properly as a problem of physical consistency. The source of this problem is the *geometric deformation* shown in Eq. (1.7), which always appears as

$$\textit{geometric deformation} = X + \alpha\, Y\ . \tag{1.9}$$

That is, there is a "sector" of the geometric deformation, generically called X, which is α-independent. Obviously this is physically problematic, since we expect to be able to control the deformation undergone by GR by varying the parameter α. It is important to remark once more that the source of this problem is solely given by the high non-linearity of the effective Einstein equations (1.3), and has nothing to do with any specific extensions of GR.

Fig. 1.2 MGD: when a GR solution is kept as a solution in the new gravitational theory, the α-independent new terms in the extended solution vanish, and the GR limit can be recovered

A method devised to solve precisely the non-trivial issue of consistency described above is the so-called *Minimal Geometric Deformation approach* (MGD) [14, 15]. The key idea is to keep under control the anisotropy induced by the extension to the Einstein theory. In particular, if we demand that the α-independent sector X in the geometric deformation (1.9) vanishes identically, the α-independent contribution to the anisotropy A in Eq. (1.8) will also vanish as a consequence. This procedure ensures that the extended theory will recover GR in the limit $\alpha = 0$. In this approach the generic expression Y in Eq. (1.9) represents the *minimal geometric deformation* undergone by the radial metric component, being the generic expression B in Eq. (1.8) the *minimal anysotropy* added to GR by the correction terms in the action (1.2) (see Figs. 1.1, 1.2).

Now, the question is how to implement the approach described above in practice. Or, more clearly, how to impose $X = 0$ in Eq. (1.9) in order to obtain a consistent extension to GR? This is accomplished when a GR solution is forced to remain a solution in the extended theory. Roughly speaking, we need to introduce the GR solution into the new theory, as far as possible. This provides the practical foundation for the MGD approach [16–24]. We want to emphasise that the GR solution used to make $X = 0$ in Eq. (1.9) will eventually be modified by using, for instance, the matching conditions at the surface of compact astrophysical object. This will in general allow us to express physical variables as functions of the deformation parameter of the theory, here generically named α. The first application of the MGD was to so called Brane-World (BW) models, and the parameter α was therefore given by the (inverse of the) brane tension. For this reason, most of this book will consider BW models of stars and other compact objects, such as black holes, although the MGD can be applied to any modification of GR of the form described above.

1.2 Extra-Dimensional Gravity: The Brane-World

Superstring/M-theory has been long considered one of the most promising candidates of quantum gravity. It describes gravity as a higher-dimensional interaction which becomes effectively four-dimensional at low enough energies. Extra-dimensional

$$S = \int \left(\frac{R}{2\,k^2} + \mathcal{L}_M \right) \sqrt{-g}\, d^4x + \alpha\,(correction)$$

$(\mathbf{a} + \mathbf{b}) + \mathbf{c} = \mathbf{a} + (\mathbf{b} + \mathbf{c})$

a geometry in which properties are preserved by parallel projection from one plane to another

3.7 PAPPUS' THEOREM AND FURTHER PROPERTIES

Multiplication in a Desarguesian affine plane is not necessarily commutative. To present an example of a plane with noncommutative multiplication, some algebraic results are necessary, so the example is deferred until Chapter 4. However, the geometric counterpart of commutativity of multiplication is *Pappus' Theorem*, which was stated as a *Euclidean* theorem in Chapter 1, Theorem 12.

■ **PAPPUS' THEOREM.** Let $\ell \cap m = O$, with P, Q, and R in ℓ; S, T, U in m; $\ell(P, T) \| \ell(Q, U)$, and $\ell(Q, S) \| \ell(R, T)$. Then $\ell(P, S) \| \ell(R, U)$.

■ **THEOREM 17.** Pappus' Theorem is true in a Desarguesian affine plane if and only if multiplication on the points of its lines is commutative.

Proof: Choosing I in ℓ so that $\ell(I, S) \| \ell(P, T)$, then PQ = R (multiplied using S (and T)). If Pappus' Theorem is true, then QP = R as well (multiplied using S (and U)). (See Fig. 3.19) Conversely, if Pappus' Theorem fails, then, relative to O and I, PQ = R but QP ≠ R, so multiplication is not commutative. ■

Pappus and Desargues

In all the examples of Desarguesian affine planes presented so far, Pappus' Theorem holds. In fact algebraic methods can be used to show that Pappus' Theorem is true in any *finite* Desarguesian affine plane, but there are (infinite) Desarguesian affine planes in which Pappus' Theorem fails. On the other hand, it has been shown that Pappus' Theorem implies that of Desargues (Hessenberg 1905).

Figure 3.19

Figure 3.20

The Distributive Laws

Besides their individual properties, addition and multiplication are related by the *distributive laws*. Because multiplication is not necessarily commutative, two distributive laws are needed. Furthermore, after laws (A + C)E = AE + CE and E(I + C) = E + EC are proved *geometrically*, an algebraic proof shows that, for an arbitrary A, E(A + C) = EA + EC.

■ **THEOREM 18.** For A, C, and E in ℓ, (A + C)E = AE + CE.

Proof: Select B $\notin \ell$. (See Fig. 3.20.)
Compute:

AE using B (and D_1).
CE using B (and D_2).
A + C using D_2 (and D_3).
(A + C)E using B (and D_4).

Let D_5 be in $\ell(D_4, (A + C)E)$, so that $\ell(A, D_3) \| \ell(AE, D_5)$. Use Desargues' Theorem on D_4, D_3, D_5 and D_1, A, AE to get $\ell(D_3, D_5) \| \ell(A, AE)$, which shows that $D_5 \in \ell(D_2, D_3)$. Now add AE + CE using D_2 (and D_5), and note that $\ell(D_2, CE) \| \ell(D_5, AE + CE)$. But this means that AE + CE = (A + C)E. ■

■ **THEOREM 19.** For C and E in ℓ, E(I + C) = E + EC.

Proof: Select B $\notin \ell$. (See Fig. 3.21.)
Compute:

EC using B (and D).
I + C using B (and D_1).
E + EC using D_1 (and D_2).

Figure 3.21

Use the converse of Desargues' Theorem on D_1, B, I and D_2, D, E which implies that $O \in \ell(D_1, D_2)$. Now use Desargues' Theorem on D_1, D_2, E + EC, and B, D_1, I + C, which gives $\ell(D, E + EC) \| \ell(B, I + C)$, whence E + EC = E(I + C). ■

Corollary. For A, C, and E in ℓ, E(A + C) = EA + EC.

Proof: If A = O, the result is immediate. If A ≠ O, then

$$\begin{aligned}(E(A + C) - EA - EC)A^{-1} &= E((A + C)A^{-1} - E - ECA^{-1} \\ &= E(I + CA^{-1}) - E - ECA^{-1} \\ &= E + ECA^{-1} - E - ECA^{-1} \\ &= O.\end{aligned}$$

Thus E(A + C) − EA − EC = O, and

$$E(A + C) = EA + EC. \qquad ■$$

The fundamental theorem of synthetic affine geometry, stated as Theorem 1 of this chapter and repeated below, has now been proved.

■ **THEOREM 20. The fundamental theorem of synthetic affine geometry.** Relative to fixed coordinates O and I, any line in a Desarguesian affine plane is a *division ring* in that its addition and multiplication are associative, and have identites, every element has an additive inverse, and every nonzero element has a multiplicative inverse. Addition is commutative, and multiplication distributes over addition.

In the next chapter we will prove that for any division ring $\mathbb{D}$, the elements of $\mathbb{D} \times \mathbb{D}$ are the points of a Desarguesian affine plane whose lines satisfy linear equations of the form $xa + yb = c$. Conversely, any Desarguesian affine plane can be so represented over (or *coordinatized by*) a division ring.

This chapter concludes with another example of an affine plane of order 5. It will be shown in Chapter 4 that this plane can be coordinatized by the field $\mathbb{Z}_5$.

□**EXAMPLE 1: An affine plane of order 5.** $\mathscr{P} = \{A, B, C, \ldots, Y\}$, and the lines are

{OIABC}	{OHMRV}
{DEFGH}	{IDNSW}
{JKLMN}	{AEJTX}
{PQRST}	{BFKPY}
{UVWXY}	{CGLQU}
{ODJPU}	{OGKTW}
{IEKQV}	{IHLPX}
{AFLRW}	{ADMQY}
{BGMSX}	{BENRU}
{CHNTY}	{CFJSV}
{OELSY}	{OFNQX}
{CDKRX}	{IGJRY}
{BHJQW}	{AHKSU}
{AGNPV}	{BDLTV}
{IFMTU}	{CEMPW}

□

EXERCISES

The following exercises pertain to the plane of order 5 given above.

1. Make addition and multiplication tables for {OIABC}.
2. Make addition and multiplication tables for $\mathbb{Z}_5$. Show that {OIABC} is *isomorphic* to $\mathbb{Z}_5$ by finding a bijection from {OIABC} to $\mathbb{Z}_5$ that preserves addition and multiplication. [*Hint:* Map O to 0 and I to 1.]
3. Find a parallelogram in $(\mathscr{P}, \mathscr{L})$ and find the point of intersection of its diagonals.
4. Find an instance of the configurations for Desargues' Theorem in $(\mathscr{P}, \mathscr{L})$.
5. Find an instance of the configuration for Pappus' Theorem in $(\mathscr{P}, \mathscr{L})$.
6. Use $(\mathscr{P}, \mathscr{L})$ to define a projective plane of order 5.

*7. Let $(\mathscr{P}', \mathscr{L}')$ be a projective plane in which Pappus' Theorem holds, and prove Desargues' Theorem as follows: Let $\ell(A, A') \cap \ell(B, B') \cap \ell(C, C') = O$, and let $A'' = \ell(B, C) \cap \ell(B', C')$, $B'' = \ell(A, C) \cap \ell(A', C')$, and $C'' = \ell(A, B) \cap \ell(A', B')$. Define $E = \ell(A, C) \cap \ell(B', C')$, $F = \ell(A, B') \cap \ell(O, C)$, $G = \ell(A, B) \cap \ell(O, E)$, and $H = \ell(A', B') \cap \ell(O, E)$. Prove that A'', B'', and C'' are collinear by using Pappus' Theorem on O, B, B' and A, E, C; then on O, A, A' and B', C', E, and finally, on A, B', F and H, G, E. [*Hint:* In the first use of Pappus' Theorem, since $\ell(B, C) \cap \ell(B', E) = A''$, $\ell(A, B') \cap \ell(O, C) = F$ and $\ell(O, E) \cap \ell(A, B) = G$, we obtain A'', F, and G collinear.]

8. Find six orthogonal partitions of the set $\{1, 2, \ldots, 25\}$.
9. Find four orthogonal Latin squares of order 5.

- Retrouver le « texte caché » de la rédaction de Youssra.

Pour aller plus loin, j'ai pensé utiliser une fonction polynôme de degré 2 pour modéliser la courbe verte qui ressemble à un morceau de parabole. J'ai tâtonné avec trois curseurs, je suis certaine que w=0, et que u et v sont opposés. Mais ça ne marche pas, je n'ai pas réussi à superposer les courbes !

- Expliquer pourquoi w=0.
- Expliquer pourquoi u et v sont opposés.

Séance 2 : analyse de la production de Mylène

Pour comprendre le problème qui me semblait compliqué, j'ai d'abord utilisé GéoGébra pour faire une figure.

Ici l'aire du triangle MPQ est égale à 0,08.

Ici l'aire du triangle MPQ est égale à 0,1.

Première question du sujet.

J'ai calculé, dans le cas général, la hauteur PH en posant x=AM.

Puis j'ai obtenu l'aire du triangle MPQ : $0{,}4x \times (1 - x) = 0{,}4x - 0{,}4x^2$

- Critiquer le résultat énoncé par Mylène :
  « l'aire du triangle MPQ est égale à $0{,}4x \times (1 - x) = 0{,}4x - 0{,}4x^2$ ».

Pág. 46 (61) - Chapater 1 – Parágrafo 6 – Spaces of constant curvature (symmetric spaces).

(f) The following manifolds are homogeneous spaces for the unitary group $U(n)$:

(i) The odd-dimensional sphere S^{2n-1}, defined in n-dimensional complex space $\mathbb{C}^n$ by the equation

$$|z^1|^2 + \cdots + |z^n|^2 = 1.$$

It is not difficult to show that in this case

$$S^{2n-1} \cong U(n)/U(n-1) \cong SU(n)/SU(n-1).$$

(ii) The complex projective space $\mathbb{C}P^{n-1}$. In this case we have

$$\mathbb{C}P^{n-1} \cong U(n)/(U(1) \times U(n-1)).$$

(iii) The complex Grassmannian manifold $G^{\mathbb{C}}_{n,k}$ consisting of the k-dimensional complex planes in $\mathbb{C}^n$ passing through the origin. Here

$$G^{\mathbb{C}}_{n,k} \cong U(n)/(U(k) \times U(n-k)).$$

5.3. Exercises

1. Let M be a homogeneous space of a Lie group G, and let H be the isotropy group. Prove that the dimension of the manifold M is the difference in the dimensions of G and H:

$$\dim M = \dim G - \dim H.$$

Compute the dimension of the Grassmannian manifold $G_{n,k}$.

2. Prove the compactness of the manifolds $V_{n,k}$ and $G_{n,k}$.

3. Let $m = (m_1, \ldots, m_k)$ be a partition of the integer n, i.e.

$$n = m_1 + \cdots + m_k, \qquad m_i \geq 0.$$

A collection of linear subspaces $\pi_0, \pi_1, \ldots, \pi_k$ of the space $\mathbb{R}^n$ is called an *m-flag* if:

(i) $\dim \pi_i - \dim \pi_{i-1} = m_i$;
(ii) $\pi_0 = 0$, $\pi_k = \mathbb{R}^n$;
(iii) $\pi_{i-1} \subset \pi_i$.

Show how the totality of all *m-flags* $F(n, m)$ can be made to serve as a homogeneous space for the group $O(n)$, and calculate its isotropy group.

§6. Spaces of Constant Curvature (Symmetric Spaces)

6.1. The Concept of a Symmetric Space

Of great interest are those manifolds endowed with a metric g_{ab} whose curvature tensor (defined in §30.1 of Part I in terms of the connexion

compatible with the metric) has identically zero covariant derivative (see §§28, 29 of Part I):

$$\nabla_s(R_{abcd}) = 0. \tag{1}$$

In any metrized space the components of the covariant derivative of the curvature tensor satisfy certain relations (namely Bianchi's identities—see Exercise 7, §30.5, Part I). However condition (1) places further severe restrictions on those components; thus, in particular, it follows from (1) that the scalar characteristics of the curvature are constant:

$$R = R^a_a = \text{const.}; \qquad R_{abcd}R^{abcd} = \text{const.}$$

It turns out also that under certain global conditions on a manifold, condition (1) implies the homogeneity of the metric g_{ab}; this is the case if the manifold is "simply connected" (see §17 below). Any manifold satisfying (1) is obtainable from some simply connected such manifold M as the quotient space (i.e. by identification) under some discrete group of motions. In this construction it can happen that the discrete group Γ in question is not central in the full isometry group of M, in which case the space M/Γ will not be homogeneous; such spaces are sometimes called "locally homogeneous" or "locally symmetric".

However our approach to symmetric spaces will be via the following definition.

6.1.1. Definition. A simply connected manifold M with a metric g_{ab} defined on it, is called a *symmetric space* (or *symmetric manifold*) if for every point x of M there exists an isometry (motion) s_x: $M \to M$ with the properties that x is an isolated fixed point of it, and that the induced map on the tangent space at x reflects (i.e. reverses) every tangent vector at x, i.e. $\xi \mapsto -\xi$. Such an isometry is called a *symmetry of M at the point x*.

The significance of the requirement in this definition that the manifold be simply connected will appear below (in §§17, 18). In the present section we shall not make use of the properties of simply connected manifolds; the reader not familiar with these properties may wish to attempt the appropriate exercises in §6.6 below, after he has studied the relevant sections of Chapter 4.

6.1.2. Lemma. *Every symmetric space satisfies condition* (1).

PROOF. Let x be any particular point of the symmetric space M and let s_x be a symmetry of M at the point x. We can choose co-ordinates in some neighbourhood of x such that at x itself we have (see §29.3 of Part I)

$$x^a = 0, \qquad g_{ab} = \delta_{ab}, \qquad \frac{\partial g_{ab}}{\partial x^a} = 0.$$

(Here we are making the (inessential) assumption that the metric is Riemannian.)

Under the symmetry s_x, at the point x the tensor $\nabla_s R_{abcd}$ goes into its negative (and the tensors g_{ab} and R_{abcd} go into themselves) simply by virtue of the symmetry property of s_x and the transformation rule for tensors. On the other hand, since s_x is actually an isometry it is clear that $\nabla_s R_{abcd}$ must go into itself at x. The only way out is for $\nabla_s R_{abcd}$ to vanish at x, as required. □

Remark. The converse of this statement (under the assumption of simple-connectedness) is also true; however, in view of the greater technical complexity of its proof, we shall not prove it here. The following discussion may, however, be illuminating. In some neighbourhood of each point x of a Riemannian manifold we can define a *local symmetry* s_x as follows: Consider the pencil of geodesics on M passing through the point x (and assumed parametrized so that for each geodesic γ we have $\gamma(0)=x$); then for sufficiently small τ set

$$s_x(\gamma(\tau))=\gamma(-\tau).$$

(Recall (e.g. from §29.2 of Part I) that in a sufficiently small neighbourhood of x the geodesics through x will intersect nowhere else.)

EXERCISE

Prove that such local transformations s_x are for all x isometries of the manifold precisely if condition (1) holds on the manifold. (*Hint*. The simplest case is $n=2$, when the curvature tensor is determined by a single scalar R. For the general case it is easiest to deduce the preservation of the curvature tensor by the transformations s_x, from the preservation of Jacobi's equation along a geodesic.)

The existence of the "symmetries" s_x for all points x of a manifold M guarantees a sufficiently large supply of isometries for M to be (locally at least) homogeneous.

6.1.3. Lemma. *A symmetric space M is locally homogeneous; i.e. around each point $x \in M$, there is a neighbourhood such that for each point $\bar{x}$ in that neighbourhood (i.e. for each $\bar{x}$ sufficiently close to x) there exists an isometry of M sending x to $\bar{x}$. For each pair of points $x, y \in M$ which can be joined by a geodesic, there exists an isometry g of M such that $g(x)=y$.*

PROOF. The first statement of the lemma follows from the second since around every point x there is a neighbourhood with the property that every point $\bar{x}$ in that neighbourhood is joined to x by a geodesic, i.e. the geodesics through x sweep out the whole neighbourhood.

For the second statement, let γ be a geodesic arc joining the points x and y, and parametrized by the natural (length) parameter τ, with $0 \le \tau \le T$, $\gamma(0)=x$, $\gamma(T)=y$. Let s_z be a symmetry of the manifold M at the point $z=\gamma(T/2)$. It follows from its symmetry property, together with the fact that it is an isometry of M, that s_z must send γ to γ, and therefore interchange x and y. (If the metric is pseudo-Riemannian of type $(1, n-1)$, and γ is an isotropic

geodesic, then we may take as τ the "affine" (called also "natural" in Chapter 5 of Part I) parameter yielded in solving the equation for the geodesics (see §29.2 of Part I). □

Remark. Since any two points of a (connected) Riemannian manifold can be joined by a broken geodesic, it follows almost immediately that a symmetric Riemannian manifold is always homogeneous.

6.2. The Isometry Group of a Manifold. Properties of Its Lie Algebra

Henceforth in this section we shall consider only homogeneous, symmetric manifolds M (hence satisfying (1)), with metric g_{ab}. The Lie group of all isometries of M will be denoted by G, and the isotropy group by H, so that we may identify M with the set of left cosets of H in G (i.e. $M = G/H$, in the notation of the preceding section).

Let $\gamma = \gamma(\tau)$ be a geodesic on M parametrized by a natural parameter τ, and write $x_0 = \gamma(0)$. For each appropriate real T we define a map $f_{T,\gamma}$: $M \to M$ by setting

$$f_{T,\gamma} = s_{x_0}^{-1} s_x,$$

where $x = \gamma(-T/2)$ (see Figure 11). This map has the following three important properties:

(i) $f_{T,\gamma}$ moves each point of γ through a time-interval T along the geodesic (as indicated in Figure 11):

$$\gamma(T) \mapsto \gamma(\tau + T);$$

(ii) $f_{T,\gamma}$ parallel transports vectors along the geodesic;

(iii) for any fixed geodesic γ, the transformations $f_{T,\gamma}$ with T variable, form a one-parameter subgroup of the isometry group G:

$$f_{T_1+T_2,\gamma} = f_{T_1,\gamma} f_{T_2,\gamma},$$
$$f_{-T,\gamma} = (f_{T,\gamma})^{-1}.$$

From the last of these properties and §3.1 above, it follows that for each geodesic γ the one-parameter subgroup $f_{T,\gamma}$ of G has the form

$$f_{T,\gamma} = \exp(TB_\gamma),$$

Figure 11

where B_γ is a certain vector in the Lie algebra $\mathfrak{g}$ of G (namely the tangent vector to the curve $f_{T,\gamma}$ at $T=0$). We denote by L^1 the linear subspace of the algebra $\mathfrak{g}$ spanned by the vectors $B_\gamma \in \mathfrak{g}$, where γ ranges over all geodesics through x_0, and by L^0 the Lie algebra of the isotropy group H_{x_0} of the point x_0. It follows (essentially from the fact that corresponding to each direction on the tangent plane to M at x_0 there is a geodesic through x_0 with that direction (see §29.2 of Part I)) that

$$\mathfrak{g} = L^0 + L^1 \quad \text{(direct sum of subspaces).} \tag{2}$$

If γ_1, γ_2 are two geodesics through the point x_0 then it can be shown that for small ε the product

$$f_{\varepsilon,\gamma_1} f_{\varepsilon,\gamma_2} f_{-\varepsilon,\gamma_1} f_{-\varepsilon,\gamma_2}$$

sends x_0 to a point whose distance from x_0 is of order ε^3. (This follows without difficulty from the properties of the Riemann curvature tensor. Verify!) We deduce from this (e.g. using formula (7) of §3.1) that we must have $[B_{\gamma_1}, B_{\gamma_2}] \in L_0$, whence $[L^1, L^1] \subset L^0$.

Suppose now that $g_T = \exp(TA)$ is a one-parameter subgroup of G leaving x_0 fixed (so that $A \in L_0$). Let γ be any geodesic through x_0, and denote by $\tilde{\gamma}$ the image of γ under the map g_ε. It then follows, again from the isometric property of the maps involved, that for small enough ε the map $g_\varepsilon f_{T,\gamma} g_{-\varepsilon}$ translates the points of the geodesic $\tilde{\gamma}$ along that geodesic (which of course also passes through x_0). Hence the tangent vector to the one-parameter subgroup $g_\varepsilon f_{T,\gamma} g_{-\varepsilon}$ (with parameter T), is in L_1. We now look for this tangent vector. From the basic facts about Lie algebras described in §3.1 it follows that for any two elements X, Y of the Lie algebra of a Lie group we have

$$\exp(tX)\exp(tY) = \exp\left(t(X+Y) + \frac{t^2}{2}[X, Y] + \text{higher-order terms}\right).$$

(This is a weak form of the "Campbell–Baker–Hausdorff formula".) It is an easy consequence of this that

$$\exp(tX)\exp(tY)\exp(-tX) = \exp(tY + t^2[X, Y] + \text{higher-order terms}).$$

Putting $t=1$, $X=\varepsilon A$, $Y = TB_\gamma$, we deduce that the desired tangent vector is $B_\gamma + \varepsilon[A, B_\gamma]$. Since $B_\gamma \in L^1$, it follows that $[A, B_\gamma] \in L^1$, whence $[L^0, L^1] \subset L^1$.

We include these facts in the following

6.2.1. Lemma. *With G and $\mathfrak{g} = L^0 + L^1$ as above, we have*

$$[L^0, L^0] \subset L^0, \qquad [L^1, L^0] \subset L^1, \qquad [L^1, L^1] \subset L^0. \tag{3}$$

A Lie algebra which decomposes as the direct sum of two subspaces satisfying (3) is called a *$\mathbb{Z}_2$-graded Lie algebra*, since (3) can be rewritten as

$$[L^i, L^j] \subset L^{(i+j) \bmod 2}. \tag{4}$$

6.2.2. Corollary. *With G as above, and $\mathfrak{g} = L^0 + L^1$ (direct) its Lie algebra, the linear operator*

$$\sigma: \mathfrak{g} \to \mathfrak{g}$$

whose restriction to L^0 is the identity map 1, and whose restriction to L^1 is the reflection -1, is a Lie algebra automorphism (i.e. also preserves commutators). (The map σ is an "involution", i.e. $\sigma^2 = 1$.)

(The converse is also true. To each involuntary automorphism σ of a Lie algebra $\mathfrak{g}$, there corresponds a $\mathbb{Z}_2$-grading $\mathfrak{g} = L^0 + L^1$ (direct sum of spaces) of the Lie algebra, where L^0 is the set of elements fixed by σ and L^1 the set of elements which σ negates.)

In view of the homogeneity of the manifold M, the local geometry around any point x_0 is determined by a scalar product on the tangent space $\mathbb{R}^n_{x_0}$ at the point. (Here $n = \dim M$.) We now elicit a certain property (familiar from Part I) which this scalar product must have.

Note first that the tangent space $\mathbb{R}^n_{x_0}$ can be identified naturally with the space $L^1 \subset \mathfrak{g}$. Let A be any element of L^0, and consider the one-parameter subgroup $g_T = \exp(TA)$. For each T we have the map

$$\mathrm{Ad}(g_T): \xi \mapsto \xi_T, \qquad \xi \in L^1.$$

As was shown in the course of proving part (i) of Theorem 3.1.4, we have

$$\xi_T = \mathrm{Ad}(g_T)(\xi) = \xi + T[A, \xi] + O(T^2),$$

whence

$$\left.\frac{d\xi_T}{dT}\right|_{T=0} = [A, \xi] = (\mathrm{ad}\, A)(\xi). \tag{5}$$

In view of the fact that g_T is an isometry of M the inner product on L^1 should be invariant under $\mathrm{Ad}(g_T)$, i.e.

$$\langle \xi_T, \eta_T \rangle = \langle \xi, \eta \rangle,$$

whence on differentiating with respect to T at $T = 0$, and using (5), we obtain

$$\langle [A, \xi], \eta \rangle + \langle \xi, [A, \eta] \rangle = 0. \tag{6}$$

This is the condition on the metric (i.e. scalar product) on $L^1 = \mathbb{R}^n_{x_0}$, that we were seeking. (Cf. the definition of a Killing metric in §24.4 of Part I.)

6.3. Symmetric Spaces of the First and Second Types

In the preceding subsection we obtained what might be called the algebraic model of a symmetric space. In principle all symmetric spaces can be classified (in the framework of the classification of compact Lie groups). In the present subsection we consider the most important examples of such spaces.

The simplest examples of (simply-connected) symmetric spaces are provided of course by the Euclidean spaces $\mathbb{R}^n$ and pseudo-Euclidean spaces $\mathbb{R}^n_{p,q}$ (where the curvature is zero). Here the group G is the full isometry group of $\mathbb{R}^n$ (or $\mathbb{R}^n_{p,q}$). (For the structure of some of these groups see §4 of Part I.) The isotropy group H is $O(n)$ (or $O(p,q)$), and the space $L^1 = \mathbb{R}^n$ consists of the translations. We have, as in the general case, $\mathfrak{g} = L^0 + L^1$, with the usual commutator relations between L^0 and L^1 (as in Lemma 6.2.1), and with the additional relation $[L^1, L^1] = 0$. Non-simply-connected symmetric spaces (earlier called "locally symmetric") can be obtained from these simply-connected ones by identification under various discrete groups Γ consisting of translations (and possibly also involving certain reflections, as for instance in the case of the Klein bottle—see §18 below).

In the remainder of our examples the group G will be semisimple. Recall from §3.1 that semisimplicity is equivalent to non-degeneracy of the Killing form on the Lie algebra $\mathfrak{g}$. Recall also that the Killing form $\langle\ ,\ \rangle$ on $\mathfrak{g}$ is defined by:

$$\langle A, B\rangle = -\operatorname{tr}(\operatorname{ad} A \operatorname{ad} B),$$

where $(\operatorname{ad} X)(\xi) = [X, \xi]$. (We shall also restrict G to being the connected component of the identity of the full isometry group.)

There are two distinct important types of simply-connected symmetric spaces with such G (even assuming the metric positive definite, i.e. Riemannian), namely:

Type I: the group G is compact and the Killing form on $\mathfrak{g}$ is positive definite. (We note here the result that a Lie group is compact if and only if it is a closed subgroup of some $O(m)$.)

Type II: the group G is non-compact and the Killing form on the Lie algebra $\mathfrak{g}$ is indefinite.

We consider the simplest (non-trivial) example of each type.

(a) The sphere S^2 is of type I. Here $G = SO(3)$, which is compact, and $H = SO(2)$.

(b) The Lobachevskian plane L^2 is of type II. Here G is the connected component of the identity of $SO(1,2)$ (shown in §13.2 of Part I to be isomorphic to $SL(2,\mathbb{R})$), and $H = SO(2)$. The Lie algebra $\mathfrak{g}$ consists of all 2×2 matrices with zero trace, and the Killing form is given by

$$\langle A, B\rangle = -\operatorname{tr}(AB).$$

As a basis for the Lie algebra we may take

$$A_1 = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, \qquad A_2 = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}, \qquad A_3 = \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix}.$$

We then have

$$A_1^2 = A_2^2 = 0, \qquad A_3^2 = 1,$$

and

$$\langle A_1, A_2\rangle = -1, \qquad \langle A_1, A_3\rangle = \langle A_2, A_3\rangle = 0,$$
$$\langle A_3, A_3\rangle = -2, \qquad \langle A_1, A_1\rangle = \langle A_2, A_2\rangle = 0.$$

It follows essentially from the fact that the matrices in $H = SO(2)$ have the form

$$\begin{pmatrix} \cos\varphi & \sin\varphi \\ -\sin\varphi & \cos\varphi \end{pmatrix},$$

that the subalgebra $L^0 \subset \mathfrak{g}$ is comprised of the matrices of the form $\lambda(A_1 - A_2)$. The subspace L^1 of $\mathfrak{g}$ is spanned by the vectors $A_1 + A_2$, A_3. It is easy to check that the inclusions (3) hold.

The restriction of the Killing form to the subspace L^1 is positive definite; this reflects the positive definiteness of the metric on the Lobachevskian plane.

EXERCISE
Investigate the general cases S^n and L^n.

6.4. Lie Groups as Symmetric Spaces

A Lie group Q endowed with a Riemannian metric invariant under left and right multiplications by group elements, can itself be regarded as a symmetric space. The isometry group of Q has a subgroup isomorphic to $Q \times Q$, whose action on Q is defined by

$$(g_1, g_2)\colon q \mapsto g_1 q g_2^{-1}.$$

The isotropy group of this action is clearly the diagonal subgroup $H = \{(q, q) | q \in Q\}$, which is isomorphic to Q: clearly $H(1) = 1$. For each q in Q the corresponding symmetry is defined by

$$s_q\colon x \mapsto q x^{-1} q.$$

(Verify that this does indeed define a symmetry.) In particular, $s_1(x) = x^{-1}$.

We shall examine in detail the case where Q is a compact connected subgroup of $SO(m)$, with the Euclidean metric

$$\langle A, B\rangle = \operatorname{tr}(AB^{\mathrm{T}}), \tag{7}$$

where B^{T} denotes the transpose of the matrix B. (Recall that it can be shown that a Lie group is compact if and only if it is a closed subgroup of some $O(m)$.)

EXERCISE
Show that the scalar product (7) is the Killing metric on $SO(m)$ determined by the Killing form on its Lie algebra (cf. §24.4 of Part I).

(The formula for the curvature of the Killing metric was derived in §30.3 of Part I. It follows from that formula that the Ricci tensor R_{ab} is positive definite. In the same subsection it was shown that the geodesics through the identity are precisely the one-parameter subgroups of Q.)

As noted in §24.4 of Part I, the group $SO(m)$ lies on the sphere of radius $\sqrt{m}$ (in the Euclidean space $\mathbb{R}^{m^2}$ of all $m \times n$ matrices with the metric (7)), since for $A \in SO(m)$, we have $AA^{\mathrm{T}} = 1$, whence $\langle A, A \rangle = m$; thus

$$SO(m) \subset S^{m^2-1}$$

6.4.1. Lemma. *The (Euclidean) scalar product (7) is invariant under right and left translations (i.e. multiplications) by elements of $SO(m)$.*

PROOF. Let $g \in SO(m)$, and let A, B be any $m \times m$ matrices. Then

$$\langle gA, gB \rangle = \operatorname{tr}(gAB^{\mathrm{T}}g^{\mathrm{T}}) = \operatorname{tr}(gAB^{\mathrm{T}}g^{-1}) = \operatorname{tr}(AB^{\mathrm{T}}) = \langle A, B \rangle,$$

and

$$\langle Ag, Bg \rangle = \operatorname{tr}(Agg^{\mathrm{T}}B^{\mathrm{T}}) = \operatorname{tr}(AB^{\mathrm{T}}) = \langle A, B \rangle,$$

whence the desired conclusion. □

6.4.2. Corollary. *The metric (7) restricted to any subgroup Q of $SO(m)$ is invariant under right and left multiplications $q \mapsto q_1 q q_2$.*

We call such a metric *bi-invariant* or *two-sided invariant*.

6.4.3. Lemma. *Every bi-invariant metric on a simple Lie group is proportional (with constant proportionality factor) to the Killing metric.*

PROOF. Let Q be a simple Lie group with bi-invariant metric $\langle\ ,\ \rangle$. The bi-invariance implies that for all elements A, B, C of the Lie algebra L of Q, and all $g_T = \exp(AT)$, we have

$$\langle \operatorname{Ad}(g_T)(B), \operatorname{Ad}(g_T)(C) \rangle = \langle B, C \rangle, \tag{8}$$

whence it follows, just as in the derivation of (6) above, that

$$\langle [A, B], C \rangle + \langle B, [A, C] \rangle = 0. \tag{9}$$

Now let $g_{ab}, \bar{g}_{ab}$ be two metrics on Q satisfying (8), (9). Then any linear combination $g_{ab} - \lambda \bar{g}_{ab}$ will also be Ad-invariant (or equivalently skew ad-invariant). Let λ_1 be any eigenvalue of the pair of quadratic forms $g_{ab}, \bar{g}_{ab}$, i.e. $\det(g_{ab} - \lambda_1 \bar{g}_{ab}) = 0$. (The symmetry of $g_{ab}, \bar{g}_{ab}$ implies that λ_1 is real.) The subspace R_{λ_1} of all eigenvectors corresponding to the eigenvalue λ_1 is easily seen (from (9)) to be a (non-zero) ideal of L, whence by the assumed simplicity of L, we must have $R_{\lambda_1} = L$. Hence $g_{ab} = \lambda_1 \bar{g}_{ab}$. Since the Killing metric satisfies (9), the desired result follows. □

6.4.4. Corollary. *Every simple subgroup Q of the group $SO(m)$ endowed with the Killing metric, can be isometrically embedded in the sphere S^{m^2-1} endowed with a metric proportional to the usual metric on the sphere.*

6.4.5. Corollary. *Since the Ricci tensor R_{ab} (determined by the Killing metric g_{ab} on a group) also satisfies* (8), (9), *it follows that for simple groups, $R_{ab} = \lambda g_{ab}$ where $\lambda = \text{const}$.*

Note finally that, as remarked above, it follows essentially from §30.3 of Part I that R_{ab} is positive definite for compact connected Lie groups. This is true also for semisimple groups, since each such group is (locally) a direct product $G_1 \times \cdots \times G_k$ of simples, and the sign of λ_i is easily determined for each of the simple factors G_i.

6.5. Constructing Symmetric Spaces. Examples

We now return to general symmetric spaces. In the notation of §6.2 above write

$$M = G/H, \qquad \mathfrak{g} = L^0 + L^1 \quad \text{(direct sum of subspaces)},$$

where M is a given symmetric space, G is its isometry group, L^0 is the Lie algebra of the isotropy group H, and L^1 is identifiable with the tangent space $\mathbb{R}^n_{x_0}$ to M at the point x_0 (fixed by H, i.e. $H = Hx_0$). Recall also that by virtue of the homogeneity of M, its metric is determined locally by a metric on L^1 satisfying (6); in what follows we shall assume the metric on M to be obtained from the Killing form on $\mathfrak{g}$ (see below).

6.5.1. Lemma. *The subspaces L^0 and L^1 of the Lie algebra $\mathfrak{g}$ are orthogonal with respect to the Killing form.*

PROOF. From Lemma 6.2.1, it is immediate that for all $A \in L^0$, $B \in L^1$ we have

$$\text{ad } A(L^0) \subset L^0, \qquad \text{ad } A(L^1) \subset L^1,$$
$$\text{ad } B(L^1) \subset L^0, \qquad \text{ad } B(L^0) \subset L^1.$$

It follows readily (using a basis of $\mathfrak{g}$ which is the union of bases for L^0 and L^1) that $\text{tr}(\text{ad } A \text{ ad } B) = 0$, as required. □

We deduce at once from this that in terms of a basis for $\mathfrak{g}$ of the kind just mentioned, the Killing form on $\mathfrak{g}$ has the form

$$(g_{ab}) = \begin{pmatrix} g^{(0)}_{\alpha\beta} & 0 \\ 0 & g^{(1)}_{\gamma\delta} \end{pmatrix}, \tag{10}$$

where α, β range over the indices of the basis for L^0, and γ, δ over the indices

of the basis for L^1. (The form $g^{(1)}_{\gamma\delta}$ is often called the *Killing form of the symmetric space M*.)

Since the Killing form (10) on $\mathfrak{g}$ satisfies (9), so also does the form $g^{(0)}_{\alpha\beta}$ on L^0. Hence by the proof of Lemma 6.4.3, if L^0 is simple then the form $g^{(0)}_{\alpha\beta}$ will be a constant multiple of the Killing form on the algebra L^0. However, in the important examples the algebra L^0 is not simple, but rather semisimple of the form $L^0 = L^0_1 \oplus L^0_2$ where L^0_1 and L^0_2 are simple. From Lemma 6.5.1 (with now L^0 in the role of $\mathfrak{g}$), we see that in this situation the restrictions of the form $g^{(0)}_{\alpha\beta}$ to the factors L^0_1, L^0_2 will be constant multiples (by λ_1, λ_2 say) of the Killing forms on those factors.

It can be seen that if H is compact and the metric $g^{(1)}_{\gamma\delta}$ is positive definite, then with respect to suitable bases for L^0 and L^1 the matrices ad A, $A \in L^0$, are skew-symmetric. Hence $\langle A, A\rangle = -\operatorname{tr}(\operatorname{ad} A)^2$ is positive, and therefore in view of

$$-\operatorname{tr}(\operatorname{ad} A)^2 = -[\operatorname{tr}(\operatorname{ad} A)^2_{L^0} + \operatorname{tr}(\operatorname{ad} A)^2_{L^1}],$$

it follows that

$$\langle A, A\rangle_{\mathfrak{g}} > \langle A, A\rangle_{L^0}. \tag{11}$$

Hence for compact H (and positive-definite metric on the symmetric space M) the restriction to L^0 (namely $g^0_{\alpha\beta}$) of the Killing form on the Lie algebra $\mathfrak{g}$, is positive definite. (Cf. the fact that the Killing form on the Lie algebra of a compact Lie group (e.g. on the Lie algebra L^0 of H) is non-negative.)

We see that in order to construct a symmetric space it essentially suffices to choose a suitable subalgebra L^0 of $\mathfrak{g}$ on which the restriction of the Killing form of the enveloping algebra $\mathfrak{g}$ is non-degenerate; then L^1 is defined as the orthogonal complement of L^0 in $\mathfrak{g}$. However the inequality (11) greatly restricts the choice of L^0: If the Killing form on $\mathfrak{g}$ is indefinite (type II) then for symmetric spaces with Riemannian metric the subalgebra $L^0 \subset \mathfrak{g}$ must be such that the restriction of the Killing form to its orthogonal complement is either positive or negative definite, and at the same time L^0 must be the Lie algebra of a compact group, and therefore of a subgroup of $SO(m)$.

Remark. A given symmetric space can be realized as a submanifold of the group G in such a way that the geodesics of M are geodesics also in the manifold G. This embedding can be obtained in any one of the following three (equivalent) ways:

(i) by considering all one-parameter subgroups of G emanating from the identity in the direction of vectors $B \in L^1$ (show that these geodesics sweep out a submanifold of G diffeomorphic to M);

(ii) via the map $\varphi: M \to G$, defined by $\varphi(x) = s_{x_0}^{-1} s_x$ (where s_{x_0}, s_x are the appropriate symmetries);

(iii) by means of an "involution" $\bar{\sigma}: G \to G$ (by which we mean an anti-automorphism of the group ($\bar{\sigma}(g_1 g_2) = \bar{\sigma}(g_2)\bar{\sigma}(g_1)$) such that the map

induced on $\mathfrak{g}$ is the identity map on L^0 and the negative of the identity map on L^1); $M \subset G$ is then the image under the map $g \mapsto g\bar{\sigma}(g^{-1})$.

EXERCISE
Show the equivalence of these embeddings.

What follows is a list of the basic examples of connected symmetric spaces of type I. (As an exercise, find in each case the corresponding direct decomposition $\mathfrak{g} = L^0 + L^1$.)

(1) $SO(2n)/U(n)$.
(2) $SU(n)/SO(n)$.
(3) $SU(2n)/Sp(n)$.
(4) $Sp(n)/U(n)$.
(5) $SO(p+q)/(SO(p) \times SO(q))$.
(6) $SU(p+q)/(SU(p) \times U(q))$.
(7) $Sp(p+q)/(Sp(p) \times Sp(q))$.

Grassmannian manifolds (including the projective spaces and spheres).

The following are examples of symmetric spaces of type II (with positive-definite metric). (The simply-connected ones among such spaces turn out to have the topology of Euclidean space $\mathbb{R}^n$.)

(1) $SO(p, q)/(SO(p) \times SO(q))$. (For $q = 1$ this is the Lobachevsky space L^p.)
(2) $SU(p, q)/(U(p) \times SU(q))$. (For $q = 1$ this is the unit ball in $\mathbb{C}^p$, as a complex manifold; if also $p = 1$, this manifold is identifiable with $L^2 \cong SU(1, 1)/U(1)$.)
(3) $Sp(p, q)/(Sp(p) \times Sp(q))$.
(4) $SL(n, \mathbb{R})/SO(n)$.
(5) $SL(n, \mathbb{C})/SU(n)$.
(6) $SO(n, \mathbb{C})/SO(n, \mathbb{R})$.

We conclude with a list of symmetric spaces of dimension 4 with metric of signature $(+ - - -)$. (These spaces are of potential importance for the general theory of relativity since (by Corollary 6.4.5) the metric g_{ab} satisfies the equation $R_{ab} - \lambda g_{ab} = 0$ (see §37.4 of Part I).

I. Spaces of constant curvature with isotropy group $H = SO(1, 3)$:

(1) Minkowski space $\mathbb{R}^4_{1,3}$.
(2) The de Sitter space $S_+ = SO(1, 4)/SO(1, 3)$; note that S_+ is homeomorphic to $\mathbb{R} \times S^3$. Here the curvature tensor R is the identity operator on the space of bivectors $\Lambda^2(\mathbb{R}^4)$: $R = 1$.
(3) The de Sitter space $S_- = SO(2, 3)/SO(1, 3)$; this space is homeomorphic to $S^1 \times \mathbb{R}^3$, and its "universal covering space" $\tilde{S}_- = \widetilde{SO}(2, 3)/\widetilde{SO}(1, 3)$ (see §18) is homeomorphic to $\mathbb{R}^4$. Here the curvature tensor $R = -1$.

II. Reducible spaces (products of spaces of constant curvature):

(1) $H = SO(3)$; $M = \mathbb{R}_+ \times M^3_{---}$, where M^3_{---} is a space of constant curvature, with signature $(- - -)$.
(2) $H = SO(1, 2)$; $M = \mathbb{R}_- \times M^3_{+--}$, where M^3_{+--} is a space of constant curvature with signature $(+ - -)$.
(3) $H = SO(2) \times SO(1, 1)$; $M = M^2_{--} \times M^2_{+-}$, the product of two 2-dimensional spaces of constant curvatures.

III. The symmetric spaces M_t of plane waves. (For these the isotropy group is abelian, and the isometry group is soluble.) In terms of a certain system of global co-ordinates the metric has the form

$$dl^2 = 2\,dx_1\,dx_4 + \underbrace{[(\cos t)x_2^2 + (\sin t)x_3^2]}_{K}\,dx_4^2 + dx_2^2 + dx_3^2,$$

$$\cos t \geq \sin t.$$

In terms of the tetrad (see §30.1 of Part I) given by the 1-forms

$$p = dx_1, \qquad q = dx_1 + K\,dx_4, \qquad x = dx_3, \qquad y = dx_4,$$

the curvature tensor is constant, of the form

$$R = -4[\cos t(p \wedge x) \otimes (p \wedge x) + \sin t(p \wedge y) \otimes (p \wedge y)].$$

Remarks. 1. A simply connected symmetric space is uniquely determined by its curvature tensor at a point. To see this let $R: \Lambda^2(V) \to \Lambda^2(V)$ be the curvature tensor, and denote by $\mathfrak{h}$ the Lie algebra of skew-symmetric linear operators on the space V generated by those operators of the form $R(x, y)$, $x, y \in V$. (Then $\mathfrak{h}$ is the Lie algebra of the isotropy group (previously denoted by L^0).) Let $\mathfrak{g}$ denote the Lie algebra $V + \mathfrak{h}$, where the commutator operation on this direct sum of spaces is defined by

$$[(u, a), (v, b)] = (av - bu, [a, b] + R(u, v)).$$

Then in terms of the pair $\mathfrak{g}$, $\mathfrak{h}$ the structure of the original symmetric space is naturally reproduced on the symmetric space $M = G/H$.

2. The problem of classifying all curvature tensors of symmetric spaces with a given isotropy group H reduces to that of finding the H-invariant tensors R of the type of the curvature tensor, for which $R(x, y)$ belongs to the Lie algebra of H for all x, y in V.

6.6. Exercises

1. Show that for symmetric spaces of type II with positive-definite metric, the dimension of the subalgebra L^0 of $\mathfrak{g}$ is equal to the number of positive squares in the Killing form on $\mathfrak{g}$.

2. Show that in the complex case (e.g. where $G = SL(n, \mathbb{C})$ or $SO(n, \mathbb{C})$) the numbers of negative and positive square terms in the complex Lie algebra $\mathfrak{g}$ are equal, and $\dim L^0 = \frac{1}{2} \dim \mathfrak{g}$. Find the subalgebra L^0 of the Lie algebra $\mathfrak{g}$ of the group $G = SL(n, \mathbb{C})$.

3. Show that for symmetric spaces of type II with positive-definite metric one always has $M \cong G/H$, where H is a maximal compact subgroup of G. Investigate the particular cases $SL(n, \mathbb{R})/SO(n)$, $SL(n, \mathbb{C})/SU(n)$.

4. Show that a simply-connected, symmetric space of type II always has the topology of Euclidean $\mathbb{R}^n$.

For the next few exercises, note that, as for Lie groups (see §30.3 of Part I), so also for symmetric spaces do we have

$$\langle R(\xi, \eta)\zeta, \tau\rangle|_{x_0} = \tfrac{1}{4}\langle [\xi, \eta], [\zeta, \tau]\rangle_{L^0}, \qquad \xi, \eta, \zeta, \tau \in \mathbb{R}^n_{x_0} = L^1.$$

5. Show that for spaces of type I, the Ricci tensor R_{ab} is positive definite, and the "sectional curvature" $\langle R(\xi, \eta)\xi, \eta\rangle$ (where ξ, η span a parallelogram of unit area) is non-negative.

6. Show that for spaces of type II the sectional curvature is non-positive. Deduce from this that a simply-connected, symmetric space of type II is topologically the same as $\mathbb{R}^n$ (assuming the metric Riemannian).

7. Decide which of the 7 symmetric spaces of type I and 6 spaces of type II listed above have non-vanishing sectional curvature. Investigate the spaces S^n, $\mathbb{C}P^n$, $\mathbb{H}P^n$ of type I, and the spaces L^n, $SU(n, 1)/U(n)$, $SL(n, \mathbb{R})/SO(n)$, $SL(n, \mathbb{C})/SU(n)$ of type II.

8. Prove that in dimensions $n = 2, 3$ the only simply-connected, symmetric spaces with positive-definite metric are L^n, S^n, $\mathbb{R}^n$. (*Hint*. Show that the isotropy group $H \subset G$ must be $SO(n)$ $(n = 2, 3)$, and thence deduce (for $n = 3$) the constancy of all sectional curvatures.)

9. Prove that a simply-connected symmetric space M with semisimple $G = G_1 \times \cdots \times G_k$ (where the G_i are simple) has the form

$$M = (G_1/H_1) \times \cdots \times (G_k/H_k),$$

with the metric decomposing as a direct product of metrics on the factors $M_i = G_i/H_i$, each of which is proportional to the Killing metric on the subspace L_i^1 of the corresponding Lie algebra $\mathfrak{g}_i = L_i^0 + L_i^1$.

§7. Vector Bundles on a Manifold

7.1. Constructions Involving Tangent Vectors

From any n-dimensional manifold M we can construct a $2n$-dimensional manifold, called the *tangent bundle* $L(M)$ of M as follows. The points of the manifold $L(M)$ are defined to be the pairs (x, ξ) where x ranges over the points

4.10 Spinor form of the Bianchi identity 245
4.11 Curvature spinors and spin-coefficients 246
4.12 Compacted spin-coefficient formalism 250
4.13 Cartan's method 262
4.14 Applications to 2-surfaces 267
4.15 Spin-weighted spherical harmonics 285

5 Fields in space–time 312
5.1 The electromagnetic field and its derivative operator 312
5.2 Einstein–Maxwell equations in spinor form 325
5.3 The Rainich conditions 328
5.4 Vector bundles 332
5.5 Yang–Mills fields 342
5.6 Conformal rescalings 352
5.7 Massless fields 362
5.8 Consistency conditions 366
5.9 Conformal invariance of various field quantities 371
5.10 Exact sets of fields 373
5.11 Initial data on a light cone 385
5.12 Explicit field integrals 393
Appendix: diagrammatic notation 424
References 435
Subject and author index 445
Index of symbols 457

78) C:\ARQ\1-Source\Volume-018---20220315\Original\017---Spinors And Space-Time, Volume 2_ Spinor And Twistor Methods In Space-Time Geometry. 2-Cambridge University Press (20.pdf → 512 pages.

Contents

	Preface	vii
	Summary of Volume 1	1
6	**Twistors**	43
6.1	The twistor equation and its solution space	43
6.2	Some geometrical aspects of twistor algebra	58
6.3	Twistors and angular momentum	68
6.4	Symmetric twistors and massless fields	75
6.5	Conformal Killing vectors, conserved quantities and exact sequences	82
6.6	Lie derivatives of spinors	101
6.7	Particle constants; conformally invariant operators	104
6.8	Curvature and conformal rescaling	120
6.9	Local twistors	127
6.10	Massless fields and twistor cohomology	139
7	**Null congruences**	169
7.1	Null congruences and spin-coefficients	169
7.2	Null congruences and space–time curvature	182
7.3	Shear-free ray congruences	189
7.4	SFRs, twistors and ray geometry	199
8	**Classification of curvature tensors**	223
8.1	The null structure of the Weyl spinor	223
8.2	Representation of the Weyl spinor on S^+	226
8.3	Eigenspinors of the Weyl spinor	233
8.4	The eigenbivectors of the Weyl tensor and its Petrov classification	242
8.5	Geometry and symmetry of the Weyl curvature	246
8.6	Curvature covariants	258
8.7	A classification scheme for general spinors	265
8.8	Classification of the Ricci spinor	275

9 Conformal infinity 291
9.1 Infinity for Minkowski space 291
9.2 Compactified Minkowski space 297
9.3 Complexified compactified Minkowski space and twistor geometry 305
9.4 Twistor four-valuedness and the Grgin index 316
9.5 Cosmological models and their twistors 332
9.6 Asymptotically simple space–times 347
9.7 Peeling properties 358
9.8 The BMS group and the structure of $\mathscr{I}^+$ 366
9.9 Energy–momentum and angular momentum 395
9.10 Bondi–Sachs mass loss and positivity 423

Appendix: spinors in n dimensions 440
References 465
Subject and author index 481
Index of symbols 499

The book of nature is written in the language of mathematics.
Galileo Galilei (1564–1642)

Obs.: Livro todo!!!

Pág. 189 – Chapter 5 – Topology of the Real Line.

Contents

1 Sets, Functions, and Cardinality 1
- 1.1 Naive Set Theory 2
- 1.2 Relation and Ordering 9
- 1.3 Functions 17
- 1.4 Cardinality 26
- 1.5 Development of Function Concept—A Historical Note 37
- References 51

2 The Real Numbers 53
- 2.1 Ordered Field $\mathbb{Q}$ 54
- 2.2 The Complete Ordered Field 65
- 2.3 Modulus Metric 78
- 2.4 Countable and Uncountable Sets in $\mathbb{R}$ 81
- References 87

3 Sequences and Series of Numbers 89
- 3.1 The Limit of a Sequence 91
- 3.2 Algebra of Convergent Sequences 103
- 3.3 Convergence Theorems 107
  - 3.3.1 Cauchy Sequences 113
  - 3.3.2 The Existence of the Set $\mathbb{R}$ 118
- 3.4 Infinite Series 120
  - 3.4.1 Tests of Convergence 124
  - 3.4.2 Arbitrary Terms Series 129
  - 3.4.3 Decimal Expansion of Real Numbers 133
- Reference 140

4 Analysis on $\mathbb{R}$ 141
- 4.1 Limit and Continuity 142
- 4.2 Differentiability 153
- 4.3 Riemann Integration 159
  - 4.3.1 Darboux Integral 161

4.3.2 Examples and Important Theorems 167
4.3.3 Properties of Riemann Integral 179
Reference 188

5 Topology of the Real Line 189
5.1 Open and Closed Set 190
5.2 Compactness 198
5.3 Connectedness 205

6 Metric Spaces 211
6.1 Some Important Metric Spaces 212
6.1.1 The Euclidean Space $\mathbb{R}^n$ 216
6.1.2 Function Spaces 225
6.1.3 Metric Subspace 230
6.2 Topology of Metric Spaces 231
6.2.1 Open Sets 234
6.2.2 Limit Points and Closed Sets 240
6.3 Convergence and Completeness 243
6.4 Compactness 252
6.5 Connectedness 258
6.5.1 Path-Connectedness 265
6.5.2 Components 267
Reference 272

7 Multivariable Analysis 273
7.1 Limit of Functions 274
7.2 Continuity of a Function 277
7.3 Differentiability 287
7.3.1 Partial Derivatives 288
7.3.2 Directional Derivatives 291
7.3.3 The Differential 292
7.4 Geometry of Curves and Surfaces 307
7.5 Two Fundamental Theorems 320
References 331

8 Sequences and Series of Functions 333
8.1 Pointwise Convergence 334
8.2 Uniform Convergence 338
8.3 Power Series 343

9 Measure and Integration 349
9.1 Measure Space 350
9.1.1 Outer Measure 361
9.1.2 Null Sets and Completion 366
9.2 Lebesgue Measure 368
9.2.1 Regularity Property 375
9.3 Lebesgue Integration 377

9.3.1 Measurable Functions 378
9.3.2 Lebesgue Integral 385
9.4 Fundamental Convergence Theorems 396
9.5 L^p Spaces 399
References 403

10 Fourier Series 405
10.1 Evolution of Modern Mathematics 407
10.2 Definitions and Examples 412
10.2.1 Sine and Cosine Fouries Series 422
10.2.2 Half-Range Fourier Series 426
10.3 Convergence Issues 430
10.3.1 Dirichlet Theorem 432
10.3.2 Gibbs Phenomenon 437
10.3.3 Convergence in Mean 439
10.3.4 Uniform Convergence 442
10.4 An Application to Infinite Series 446
References 449

Appendix: Mathematical Logic 451

→ 258 pages.

Contents

1 Metric Spaces 1
1.1 Metrics 1
1.1.1 Rationale for Metrics 1
1.1.2 Defining Metric Space 2
1.1.3 Exercises 5
1.2 Examples of Metric Spaces 6
1.2.1 Normed Spaces 6
1.2.2 Subspaces 8
1.2.3 Examples; Not Subspaces of Normed Spaces 9
1.2.4 Pseudometrics 9
1.2.5 Cauchy-Schwarz, Hölder, Minkowski 11
1.2.6 Exercises 14
1.3 Cantor's Middle Thirds Set 16
1.3.1 Exercises 19
1.4 The Normed Spaces of Functional Analysis 20
1.4.1 Sequence Spaces 20
1.4.2 Function Spaces 22
1.4.3 Spaces of Continuous Functions 23
1.4.4 Spaces of Integrable Functions 23
1.4.5 Hölder's and Minkowski's Inequalities for Integrals 24
1.4.6 Exercises 25

2 Basic Theory of Metric Spaces 29
2.1 Balls in a Metric Space 29
2.1.1 Limit of a Convergent Sequence 30
2.1.2 Uniqueness of the Limit 31
2.1.3 Neighbourhoods 32
2.1.4 Bounded Sets 32
2.1.5 Completeness; a Key Concept 32
2.1.6 Exercises 35

2.2 Open Sets, and Closed 37
2.2.1 Open Sets 38
2.2.2 Union and Intersection of Open Sets 39
2.2.3 Closed Sets 39
2.2.4 Union and Intersection of Closed Sets 40
2.2.5 Characterisation of Open and Closed Sets by Sequences ... 41
2.2.6 Interior, Closure and Boundary 42
2.2.7 Limit Points of Sets 43
2.2.8 Characterisation of Closure by Limit Points 43
2.2.9 Subspaces 45
2.2.10 Open and Closed Sets in a Subspace 45
2.2.11 Exercises 47
2.3 Continuous Mappings 52
2.3.1 Defining Continuity 52
2.3.2 New Views of Continuity 53
2.3.3 Limits of Functions 55
2.3.4 Characterising Continuity by Sequences 57
2.3.5 Lipschitz Mappings 57
2.3.6 Examples of Continuous Functions 58
2.3.7 Exercises 59
2.4 Continuity of Linear Mappings 63
2.4.1 Continuity Criterion 64
2.4.2 Operator Norms 66
2.4.3 Exercises 68
2.5 Homeomorphisms and Topological Properties 70
2.5.1 Equivalent Metrics 72
2.5.2 Exercises 73
2.6 Topologies and σ-Algebras 74
2.6.1 Order Topologies 77
2.6.2 Exercises 79
2.6.3 Pointers to Further Study 82
2.7 ($\Diamond$) Mazur-Ulam 82
2.7.1 Exercises 84

3 Completeness of the Classical Spaces 87
3.1 Coordinate Spaces and Normed Sequence Spaces 87
3.1.1 Completeness of $\mathbb{R}^n$ 87
3.1.2 Completeness of ℓ^p 88
3.1.3 Exercises 90
3.2 Product Spaces 90
3.2.1 Finitely Many Factors 91
3.2.2 Infinitely Many Factors 91
3.2.3 The Space $2^{\mathbb{N}_+}$ and the Cantor Set 93
3.2.4 Subspaces of Complete Spaces 95
3.2.5 Exercises 96

3.3 Spaces of Continuous Functions 99
3.3.1 Uniform Convergence 99
3.3.2 Series in Normed Spaces 101
3.3.3 The Weierstrass M-Test 103
3.3.4 The Spaces $C(\mathbb{R})$ and $C^p(\mathbb{R})$ 103
3.3.5 Exercises 105
3.4 (◊) Rearrangements 108
3.4.1 Vector Series 108
3.4.2 Exercises 111
3.4.3 Pointers to Further Study 111
3.5 (◊) Invertible Operators 112
3.5.1 Fredholm Integral Equation 115
3.5.2 Exercises 116
3.5.3 Pointers to Further Study 118
3.6 (◊) Tietze 118
3.6.1 Formulas for an Extension 121
3.6.2 Exercises 121
3.6.3 Pointers to Further Study 123

4 Compact Spaces 125
4.1 Sequentially Compact Spaces 125
4.1.1 Continuous Functions on Sequentially Compact Spaces 126
4.1.2 Bolzano-Weierstrass in $\mathbb{R}^n$ 126
4.1.3 Sequentially Compact Sets in $\mathbb{R}^n$ 127
4.1.4 Sequentially Compact Sets in Other Spaces 127
4.1.5 The Space $C(M)$ 128
4.1.6 Exercises 129
4.2 The Correct Definition of Compactness 130
4.2.1 Thoughts About the Definition 131
4.2.2 Compact Spaces and Compact Sets 132
4.2.3 Continuous Functions on Compact Spaces 134
4.2.4 Uniform Continuity 135
4.2.5 Exercises 136
4.3 Equivalence of Compactness and Sequential Compactness 137
4.3.1 Relative Compactness 141
4.3.2 Local Compactness 142
4.3.3 Exercises 143
4.4 Finite Dimensional Normed Vector Spaces 150
4.4.1 Exercises 153
4.5 (◊) Ascoli 154
4.5.1 Peano's Existence Theorem 157
4.5.2 Exercises 160
4.5.3 Pointers to Further Study 162

5 Separable Spaces 163
5.1 Dense Subsets of a Metric Space 163
5.1.1 Defining a Vector-Valued Integral 165
5.1.2 Exercises 168
5.2 Separability 171
5.2.1 Second Countability 172
5.2.2 Exercises 173
5.3 (◊) Weierstrass 176
5.3.1 Exercises 180
5.3.2 Pointers to Further Study 182
5.4 (◊) Stone-Weierstrass 182
5.4.1 Exercises 185
5.4.2 Pointers to Further Study 186

6 Properties of Complete Spaces 187
6.1 Cantor's Nested Intersection Theorem 187
6.1.1 Categories 188
6.1.2 Exercises 190
6.2 (◊) Genericity 193
6.2.1 Exercises 196
6.2.2 Pointers to Further Study 199
6.3 (◊) Nowhere Differentiability 199
6.3.1 Exercises 202
6.3.2 Pointers to Further Study 203
6.4 Fixed Points 203
6.4.1 Exercises 204
6.5 (◊) Picard 206
6.5.1 Exercises 209
6.6 (◊) Zeros 209
6.6.1 Exercises 213
6.6.2 Pointers to Further Study 216
6.7 Completion of a Metric Space 216
6.7.1 Other Ways to Complete a Metric Space 218
6.7.2 Exercises 218

7 Connected Spaces 219
7.1 Connectedness 219
7.1.1 Connected Sets 221
7.1.2 Rules for Connected Sets 221
7.1.3 Connected Subsets of $\mathbb{R}$ 223
7.1.4 Exercises 223
7.2 Continuous Mappings and Connectedness 224
7.2.1 Continuous Curves 224
7.2.2 Arcwise Connectedness 225
7.2.3 Exiting a Set 226
7.2.4 Exercises 227

7.3 Connected Components 229
7.3.1 Examples of Connected Components 229
7.3.2 Arcwise Connected Components 232
7.3.3 Exercises 232
7.4 (◊) Peano 236
7.4.1 Exercises 236
7.4.2 Pointers to Further Study 237

Pág. 01(20) – Chapter 01 - Digital Rolling Test of Cycloidal Hypoid Gears Based on Measuring Tooth Surface Data

Pág. 05(24) -

Fig. 1.3 Schematic diagram of the verification area on the real tooth surface model

Pág. 07(25) -

Fig. 1.5 Meshing coordinate systems

$$= M_{s1} P_1(u_1, v_1)$$

$$M_{s_p2} = M_{s2} P_2(u_2, v_2)$$

where

$$M_{p1} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & \cos(\varphi_1) & \sin(\varphi_1) & 0 \\ 0 & -\sin(\varphi_1) & \cos(\varphi_1) & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}$$

$$M_{qp} = \begin{bmatrix} 1 & 0 & 0 & H_1 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}$$

$$M_{rq} = \begin{bmatrix} \cos(\Sigma) & 0 & -\sin(\Sigma) & 0 \\ 0 & 1 & 0 & 0 \\ \sin(\Sigma) & 0 & \cos(\Sigma) & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}$$

$$M_{sr} = \begin{bmatrix} 1 & 0 & 0 & H_2 \\ 0 & 1 & 0 & -V \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}$$

$$M_{s2} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & \cos(\varphi_2) & \sin(\varphi_2) & 0 \\ 0 & -\sin(\varphi_2) & \cos(\varphi_2) & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}$$

φ_1 and φ_2 are the rotary angles of pinion and gear. M_{s1} and M_{s2} are the transformation matrices from measuring coordinate system S_1 and S_2 to the meshing coordinate system S_s for the pinion and gear. S_p, S_q, and S_r are auxiliary coordinate systems. H_1 and H_2 are the axial settings of pinion and gear. Σ is the shaft angle. V is the pinion offset distance.

→ It can be of no practical use
to know that π is irrational, but if we can know,
it surely would be intolerable not to know.
E.C. Titchmarsh
Die ganzen Zahlen hat der liebe Gott gemacht,
alles andere ist Menschenwerk.
Leopold Kronecker

Books-07-2022/20220413/
Important/
A History of Pythagoreanism.pdf
Pág. 13 (21)

Pythagorean analysis of the similarities between numbers and things inspired by the advancement of the mathemata, which Aristotle attributes to them;

Pág. 105 (113) -
Plato ascribes to Theodorus
(discoveries were further incorporated)
a proof of irrationality of the magnitudes between $\sqrt{3}$ to $\sqrt{17}$

Carve up! Irrationals, binomials

(Tht. 147 d = DK 43 A 4),
which means that
(signifies que)
Theodorus relied on the proof
of the irrationality of $\sqrt{2}$
that was found by Hippasus.[62]

62 – For reconstructions of
Theodorus's proof, see, e.g.,
Heath 1921: I. 202ff;
Knorr 1975: 109ff

Obs: Heath, T. L. 1921
A History of Greek Mathematics

A History of Pythagoreanism.

Heath – Vol I Pág 202

outro assunto!

This course will be best
described when we come
to deal with the problem of
squaring the circle (Chapter VII).

here we need only remark that it implies the proposition that the lengths of arcs in a circle are proportional to the angles subtended by them at the centre

(Eucl. VI. 33)

trisecting any rectilineal angle ...

and these problems are not what the Greeks called 'plane' problems, i.e.,

they cannot be solved by means of the ruler and compasses.

Hippasus — Pág. 65 (85)

Chapter III

Pythagorean Arithmetic

Hippasus → ... for making known the discovery of the irrational or incommensurable.

Pág. 160 (180) –
Hippasus
who was a Pythagorean but,
owing to his being the first
to publish and write down the
(construction of the) sphere
with (ék, from)
the twelve pentagons, perished
by shipwreck for his impiety,
but received credit for the
discovery...

333,3 −
250
83,3

333,3 − 100
83,3 − x
$= 25,\overline{0015}\ (\approx \frac{1}{4})$

off: $\frac{83,3}{333,3} =$
$0,\overline{2499}$

$2^1 = 2$

$2^2 = 4$

$\times 2$

$2^3 = 8$

$\times 2$

Se $2^3 = 8$

$\therefore$

$1^3 = 4$

$1^1 = 1 \quad 1^2 = 1 \quad 1^3 = 1$ (Wrong!!!)

$1^1 = 1 \quad 1^2 = 2 \quad 1^3 = 4$

$2^1 = 2 \quad 2^2 = 4 \quad 2^3 = 8$

→ Wrong!!! do ponto de vista numérico, mas volumetricamente funciona

$1\,m^3 = 1000$ litros (3d)

↓

\begin{text}
\HUGE
\end{text}

A hermenêutica matemática tem por objetivo conhecer o real sentido e valor das ~~cada~~ palavras, symbolos and numbers needed to express mathematical ideas.

⇒ A hermenêutica matemática ~~tem~~ é uma ciência ~~que tem~~ da interpretação das palavras, símbolos e números necessários para expressar ideias matemáticas.

O conhecimento do real ~~do~~ sentido e valor da linguagem matemática tem por objetivo exprimir de forma precisa os conceitos inerentes a cada palavra empregada no texto matemático.

exemplos

Nenhuma palavra, símbolo ou número está no texto sem significado ou função, pois cada uma delas contém com a ideia que se quer

demostrar
construir, defender, refutar
ou explicar.

$1^3 = 3$ ou 4

$\underset{(01)}{1} \times \underbrace{\underset{(02)}{1} \times \underset{(03)}{1}}_{\text{3 unidades}} = \boxed{3}$ (3 unidades)

Usando da mesma lógica:

$2^3 = 8$

$\underbrace{2 \times 2 \times 2}_{\text{3 elementos}} = 8$ (valor em unidades)

O número 2 é o dobro de 1, portanto, se $2^3 = 8$ e o número 1 é a metade de 2^3, portanto, $1^3 = \boxed{4}$

Prosseguindo (com base na raiz no número geral (expoente))

$3^3 = 27$

$3 \times 3 \times 3 = 27 \Rightarrow 1 = \frac{1}{3}$ de 27

$\frac{27}{3} = \boxed{9}$

$4^3 = 64 \Rightarrow 1 \Rightarrow \frac{1}{4}$ de $64 = \frac{64}{4} = \boxed{16}$

$5^3 = 75 \Rightarrow 1 = \frac{1}{5}$ de $125 = \frac{125}{5} = \boxed{25}$

$6^3 = 216 \Rightarrow 1 = \frac{1}{6}$ de $216 = \frac{216}{6} = \boxed{36}$

$7^3 = 343 \Rightarrow 1 = \frac{1}{7}$ de $343 = \frac{343}{7} = \boxed{49}$

$8^3 = 512 \Rightarrow 1 = \frac{1}{8}$ de $512 = \frac{512}{8} = \boxed{64}$

$9^3 = 729 \Rightarrow 1 = \frac{1}{9}$ de $729 = \frac{729}{8} = \boxed{81}$

$10^3 = 1000 \Rightarrow 1 = \frac{1}{10}$ de $1000 = \frac{1000}{10} = \boxed{100}$

Divisão por 4:

$1 \times 1 \times 1 = 4$

$2 \times 2 \times 2 = 8 \rangle \frac{8}{4} = 2$ (dobro)

$3 \times 3 \times 3 = 27 \rangle \frac{27}{8} = 3,375$

$4 \times 4 \times 4 = 64 \rangle \frac{64}{27} = 2,\overline{370}$

$5 \times 5 \times 5 = 125 \rangle \frac{125}{64} = 1,953125$ (1,953125)

$6 \times 6 \times 6 = 216 \rangle \frac{216}{75} = 2,88$

$7 \times 7 \times 7 = 343 \rangle \frac{343}{216} = 1,58796296$

$8 \times 8 \times 8 = 512 \rangle \frac{512}{343} = 1,49271137$

$9 \times 9 \times 9 = 729 \rangle \frac{729}{512} = 1,42382812$

$10 \times 10 \times 10 = 1000 \rangle \frac{1000}{729} = 1,37174211$

entre os números primos

$\approx \sqrt[7]{2} = 1,4142137$

Relação direta entre os números.

$1 \rightarrow 2 \Rightarrow 8 \div 4 = 2$
$1 \rightarrow 3 \Rightarrow 27 \div 4 = 6,75$
$1 \rightarrow 4 \Rightarrow 64 \div 4 = 16$
$1 \rightarrow 5 \Rightarrow 125 \div 4 = 31,25$
$1 \rightarrow 6 \Rightarrow 216 \div 4 = 54$
$1 \rightarrow 7 \Rightarrow 343 \div 4 = 85,75$
$1 \rightarrow 8 \Rightarrow 512 \div 4 = 128$
$1 \rightarrow 9 \Rightarrow 729 \div 4 = 182,25$
$1 \rightarrow 10 \Rightarrow 1000 \div 4 = 250$

Se em vez de $4 \rightarrow 3$

$1 \times 1 \times 1 = 3$

$8 \div 3 = 2,\overline{6}$
$27 \div 3 = 9$
$64 \div 3 = 21,\overline{3}$
$125 \div 3 = 41,\overline{6}$ $(41,\overline{6})$
$216 \div 3 = 72$
$343 \div 3 = 114,\overline{3}$
$512 \div 3 = 170,\overline{6}$
$729 \div 3 = 243$
$1000 \div 3 = 333,\overline{3}$

Voltando:

$1^3 = 4$ $\left(\frac{8}{2} = 4\right)$

$2^3 = 8 \rightarrow$ 2 é o dobro de 1

$6,75 - 2 = 4,75$
$16 - 6,75 = 9,25$
$31,25 - 16 = 15,25$
$54 - 31,25 = 22,75$
$85,75 - 54 = 31,75$
$128 - 85,75 = 42,25$
$182,25 - 128 = 54,25$
$250 - 182,25 = 67,75$

$\Downarrow$

$4,75 > 4,5$
$9,25 > 6$
$15,25 > 7,5$
$22,75 > 9$
$31,75 > 10,5$
$42,25 > 12$
$54,25 > 13,5$
$67,75 > 15$

diferença de 1,5 ou 1,5

$1^3 = 4$

$2^3 = 8 \rightarrow 2$ é o dobro $1 = 8 \div 4 = 2$

$3^3 = 27 \rightarrow 3$ é o triplo $1 = 27 \div 4 = 6{,}75$

$4^3 = 64 \rightarrow 4 \times 1 = 64 \div 4 =$

$5^3 = 125 \rightarrow 5 \times 1 = 125 \div 4 =$

$6^3 = 216 \rightarrow 6 \times 1 = 216 \div 4 =$

$7^3 = 343 \rightarrow 7 \times 1 = 343 \div 4 =$

$8^3 = 512 \rightarrow 8 \times 1 = 512 \div 4 =$

$9^3 = 729 \rightarrow 9 \times 1 = 729 \div 4 =$

$10^3 = 1000 \rightarrow 10 \times 1 = 1000 \div 4 =$

corrigindo

$8 \div 4 =$ erro

$8 \div 2 = 4 \leftarrow (1^3)$ > 5

$27 \div 3 = 9$ > 7

$64 \div 4 = 16$ > 9

$125 \div 5 = 25$ > 11

$216 \div 6 = 36$ > 13

$343 \div 7 = 49$ > 15

$512 \div 8 = 64$ > 17

$729 \div 9 = 81$ > 19

$1000 \div 10 = 100$

Correto

O valor aumenta de 2 em 2

conserto:

Usando a multiplicação partindo-se do número $1^3 = 4$, depois faremos $1^3 = 3$

$1^3 = \boxed{4}$

$2^3 = \boxed{4} \times 2 = 8$

$3^3 = \boxed{4} \times 3 = 12$

$4^3 = \boxed{4} \times 4 = 16$

$5^3 = \boxed{4} \times 5 = 20$

$6^3 = \boxed{4} \times 6 = 24$

$7^3 = \boxed{4} \times 7 = 28$

$8^3 = \boxed{4} \times 8 = 32$

$9^3 = \boxed{4} \times 9 = 36$

$10^3 = \boxed{4} \times 10 = 40$

2x

x3

mantendo-se a proporção (o) raciocínio equivocado com potenciação

estudar!!!

mas numericamente está correto. (?) checar!!!

Valores reais:

4	$8 \div 4 = 2$
8	
27	$27 \div 4 = 6{,}75$
64	$64 \div 4 = 16$
125	$125 \div 4 = 31{,}25$
216	$216 \div 4 = 54$
343	$343 \div 4 = 85{,}75$
512	$512 \div 4 = 128$
729	$729 \div 4 = 182{,}25$
1000	$1000 \div 4 = 250$

discrepância.

Simulações:

$1^3 = 1 \times 1 \times 1 = 3$

$2^3 = 2 \times 2 \times 2 = 8$ $\Big\}$ $8 \div 3 = 2,\overline{6}$

$3^3 = 27 \rightarrow 27 \div 3 = 9$

$4^3 = 64 \rightarrow 64 \div 3 = 21,\overline{3}$

$5^3 = 125 \rightarrow 125 \div 3 = 41,\overline{6}$

$6^3 = 216 \rightarrow 216 \div 3 = 72$

$7^3 = 343 \rightarrow 343 \div 3 = 114,\overline{3}$

$8^3 = 512 \rightarrow 512 \div 3 = 170,\overline{6}$

$9^3 = 729 \rightarrow 729 \div 3 = 243$

$10^3 = 1000 \rightarrow 1000 \div 3 = 333,\overline{3}$

Aprofundando:

começando desde o primeiro

1

$1^3 = 4$

$1^3 = 4 \Rightarrow 4 \div 1 = 4$

$4 - 4 = 0$ relação direta perfeita!!! (sem relação direta)

$2^3 = 8 \Rightarrow 8 \div 2 = 4$

$3^3 = 27 \Rightarrow 27 \div 3 = 9 \rangle 5$

$4^3 = 64 \Rightarrow 64 \div 4 = 16 \rangle 7$

$5^3 = 125 \Rightarrow 125 \div 5 = 25 \rangle 9$

$6^3 = 216 \Rightarrow 216 \div 6 = 36 \rangle 11$

$7^3 = 343 \Rightarrow 343 \div 7 = 49 \rangle 13$

$8^3 = 512 \Rightarrow 512 \div 8 = 64 \rangle 15$

$9^3 = 729 \Rightarrow 729 \div 9 = 81 \rangle 17$

$10^3 = 1000 \Rightarrow 1000 \div 10 = 100 \rangle 19$

aumento de 2 em 2

Obs:

Mantendo-se esta constante e retrocedendo até o número 1,

$1^3 = 1$, pois $2^3 = 8 \div 2 = 4$

e não $1^3 = 3$ ou 4

$4 - 3 = 1$

Comparando → 3 e 4

4	$8 \div 4 = 2$	3	$8 \div 3 = 2,6$
8		8	
27	$27 \div 4 = 6,75$	27	$27 \div 3 = 9$
64	$64 \div 4 = 16$	64	$64 \div 3 = 21,\overline{3}$
125	$125 \div 4 = 31,25$	125	$125 \div 3 = 41,\overline{6}$
216	$216 \div 4 = 54$	216	$216 \div 3 = 72$
343	$343 \div 4 = 85,75$	343	$343 \div 3 = 114,\overline{3}$
512	$512 \div 4 = 128$	512	$512 \div 3 = 170,\overline{6}$
729	$729 \div 4 = 182,25$	729	$729 \div 3 = 243$
1000	$1000 \div 4 = 250$	1000	$1000 \div 3 = 333,\overline{3}$

20220303

Brane → an extended object with any given number of dimensions, of which strings in string theory are examples with one dimension.

Our Universe is a 3-brane

"Você não tem nada a será feliz" → Comer mistura → Fonsa Mundial.

20220304

$1^3 = 4 \qquad 2^3 = 8$

lógico!!!

$1\,m^3 = 1000$

$\frac{1\,m^3}{3} = 333{,}\overline{3} \qquad \frac{1\,m^3}{1^3} = \frac{1000}{4}$

$= 250$

3

333,3 –
250
83,3

333,3 – 100
83,3 – x
$= 25{,}\overline{0015}$ ($\approx \frac{1}{4}$)

off $\frac{83{,}3}{333{,}3} =$

$0{,}\overline{2499}$

$2^1 = 2$

$2^2 = 4$

$\times 2$

$\times 2$

$2^3 = 8$

se $2^3 = 8$

$\therefore$

$1^3 = 4$

$1^1 = 1 \quad 1^2 = 1 \quad 1^3 = 1$ (Wrong!!!)

$1^1 = 1 \quad 1^2 = 2 \quad 1^3 = 4$

$2^1 = 2 \quad 2^2 = 4 \quad 2^3 = 8$

→ Wrong!!! do ponto de vista numérico, mas volumetricamente funciona

$1\,m^3 = 1000$ litros (3d)

$1^3 = 3$ ou 4

$\underset{(01)}{1} \times \underbrace{\underset{(02)}{1} \times \underset{(03)}{1}}_{3 \text{ unidades}} = \boxed{3}$ (3 unidades)

Usando da mesma lógica:

$2^3 = 8$

$\underbrace{2 \times 2 \times 2}_{3 \text{ elementos}} = 8$ (valor em unidades)

O número 2 é o dobro de 1, portanto, se $2^3 = 8$ e o número 1 é a metade de 2^3, portanto, $1^3 = \boxed{4}$

Prosseguindo (com base na razão no número geral (exponenciando))

$3^3 = 27$

$3 \times 3 \times 3 = 27 \Rightarrow 1 = \frac{1}{3}$ de 27

$\frac{27}{3} = \boxed{9}$

$4^3 = 64 \Rightarrow 1 \Rightarrow \frac{1}{4}$ de $64 = \frac{64}{4} = \boxed{16}$

$5^3 = 75 \Rightarrow 1 = \frac{1}{5}$ de $125 = \frac{125}{5} = \boxed{25}$

$6^3 = 216 \Rightarrow 1 = \frac{1}{6}$ de $216 = \frac{216}{6} = \boxed{36}$

$7^3 = 343 \Rightarrow 1 = \frac{1}{7}$ de $343 = \frac{343}{7} = \boxed{49}$

$8^3 = 512 \Rightarrow 1 = \frac{1}{8}$ de $512 = \frac{512}{8} = \boxed{64}$

$9^3 = 729 \Rightarrow 1 = \frac{1}{9}$ de $729 = \frac{729}{8} = \boxed{81}$

$10^3 = 1000 \Rightarrow 1 = \frac{1}{10}$ de $1000 = \frac{1000}{10} = \boxed{100}$

Divisão por 4:

$1 \times 1 \times 1 = 4$

$2 \times 2 \times 2 = 8 \rangle \frac{8}{4} = 2$ (dobro)

$3 \times 3 \times 3 = 27 \rangle \frac{27}{8} = 3{,}375$

$4 \times 4 \times 4 = 64 \rangle \frac{64}{27} = 2{,}370$

$5 \times 5 \times 5 = 125 \rangle \frac{125}{64} = 1{,}95$ (1,953125)

$6 \times 6 \times 6 = 216 \rangle \frac{216}{75} = 2{,}88$

$7 \times 7 \times 7 = 343 \rangle \frac{343}{216} = 1{,}58796296$

$8 \times 8 \times 8 = 512 \rangle \frac{512}{343} = 1{,}49271137$

$9 \times 9 \times 9 = 729 \rangle \frac{729}{512} = 1{,}42382812$

$10 \times 10 \times 10 = 1000 \rangle \frac{1000}{729} = 1{,}371742211$

entre os números primos

$\approx \sqrt[12]{2} = 1{,}4142137$

Relação direta entre os números.

$1 \rightarrow 2 \Rightarrow 8 \div 4 = 2$
$1 \rightarrow 3 \Rightarrow 27 \div 4 = 6,75$
$1 \rightarrow 4 \Rightarrow 64 \div 4 = 16$
$1 \rightarrow 5 \Rightarrow 125 \div 4 = 31,25$
$1 \rightarrow 6 \Rightarrow 216 \div 4 = 54$
$1 \rightarrow 7 \Rightarrow 343 \div 4 = 85,75$
$1 \rightarrow 8 \Rightarrow 512 \div 4 = 128$
$1 \rightarrow 9 \Rightarrow 729 \div 4 = 182,25$
$1 \rightarrow 10 \Rightarrow 1000 \div 4 = 250$

Se em vez de $4 \rightarrow 3$

$1 \times 1 \times 1 = 3$

$8 \div 3 = 2,\overline{6}$
$27 \div 3 = 9$
$64 \div 3 = 21,\overline{3}$
$125 \div 3 = 41,\overline{6}$ $(41,\check{6})$
$216 \div 3 = 72$
$343 \div 3 = 114,\overline{3}$
$512 \div 3 = 170,\overline{6}$
$729 \div 3 = 243$
$1000 \div 3 = 333,\overline{3}$

Voltando:

$1^3 = 4$ $\left(\frac{8}{2} = 4\right)$

$2^3 = 8 \rightarrow$ 2 é o dobro de 1

6,75 - 2 = 4,75
16 - 6,75 = 9,25
31,25 - 16 = 15,25
54 - 31,25 = 22,75
85,75 - 54 = 31,75
128 - 85,75 = 42,25
182,25 - 128 = 54,25
250 - 182,25 = 67,75

4,75 > 4,5
9,25 > 6
15,25 > 7,5
22,75 > 9
31,75 > 10,5
42,25 > 12
54,25 > 13,5
67,75 > 13,5

diferença de 1,5 em 1,5

$1^3 = 4$

$2^3 = 8 \rightarrow 2$ é o dobro $1 = 8 \div 4 = 2$

$3^3 = 27 \rightarrow 3$ é o triplo $1 = 27 \div 4 = 6{,}75$

$4^3 = 64 \rightarrow 4 \times 1 = 64 \div 4 =$

$5^3 = 125 \rightarrow 5 \times 1 = 125 \div 4 =$

$6^3 = 216 \rightarrow 6 \times 1 = 216 \div 4 =$

$7^3 = 343 \rightarrow 7 \times 1 = 343 \div 4 =$

$8^3 = 512 \rightarrow 8 \times 1 = 512 \div 4 =$

$9^3 = 729 \rightarrow 9 \times 1 = 729 \div 4 =$

$10^3 = 1000 \rightarrow 10 \times 1 = 1000 \div 4 =$

corrigindo

$8 \div 4 =$ erro

$8 \div 2 = 4 \leftarrow (1^3)$ > 5

$27 \div 3 = 9$ > 7

$64 \div 4 = 16$ > 9

$125 \div 5 = 25$ > 11

$216 \div 6 = 36$ > 13

$343 \div 7 = 49$ > 15

$512 \div 8 = 64$ > 17

$729 \div 9 = 81$ > 19

$1000 \div 10 = 100$

~~outro erro~~

Correto

O valor aumenta de 2 em 2

correto:

Usando a multiplicação partindo-se do número $1^3 = 4$, depois faremos $1^3 = 3$

$1^3 = \boxed{4}$

$2^3 = \boxed{4} \times 2 = 8$

$3^3 = \boxed{4} \times 3 = 12$

$4^3 = \boxed{4} \times 4 = 16$

$5^3 = \boxed{4} \times 5 = 20$

$6^3 = \boxed{4} \times 6 = 24$

$7^3 = \boxed{4} \times 7 = 28$

$8^3 = \boxed{4} \times 8 = 32$

$9^3 = \boxed{4} \times 9 = 36$

$10^3 = \boxed{4} \times 10 = 40$

2x

x3

mantendo-se a proporção, (o) raciocínio equivocado com potência

estudar!!!

mas numericamente está correto. (?) Checar!!!

Valores reais:

4	$8 \div 4 = 2$
8	
27	$27 \div 4 = 6{,}75$
64	$64 \div 4 = 16$
125	$125 \div 4 = 31{,}25$
216	$216 \div 4 = 54$
343	$343 \div 4 = 85{,}75$
512	$512 \div 4 = 128$
729	$729 \div 4 = 182{,}25$
1000	$1000 \div 4 = 250$

discrepância.

Simulações:

$1^3 = 1 \times 1 \times 1 = 3$

$2^3 = 2 \times 2 \times 2 = 8$ $\Big\}$ $8 \div 3 = 2,\overline{6}$

$3^3 = 27 \rightarrow 27 \div 3 = 9$

$4^3 = 64 \rightarrow 64 \div 3 = 21,\overline{3}$

$5^3 = 125 \rightarrow 125 \div 3 = 41,\overline{6}$

$6^3 = 216 \rightarrow 216 \div 3 = 72$

$7^3 = 343 \rightarrow 343 \div 3 = 114,\overline{3}$

$8^3 = 512 \rightarrow 512 \div 3 = 170,\overline{6}$

$9^3 = 729 \rightarrow 729 \div 3 = 243$

$10^3 = 1000 \rightarrow 1000 \div 3 = 333,\overline{3}$

Aprofundando:

começando desde o primeiro

1

$1^3 = 4$

$1^3 = 4 \Rightarrow 4 \div 1 = 4$

$2^3 = 8 \Rightarrow 8 \div 2 = 4$ > $4-4 = 0$

relação direta perfeita!!! (sem relação direta)

$3^3 = 27 \Rightarrow 27 \div 3 = 9$ > 5

$4^3 = 64 \Rightarrow 64 \div 4 = 16$ > 7

$5^3 = 125 \Rightarrow 125 \div 5 = 25$ > 9

$6^3 = 216 \Rightarrow 216 \div 6 = 36$ > 11

$7^3 = 343 \Rightarrow 343 \div 7 = 49$ > 13

$8^3 = 512 \Rightarrow 512 \div 8 = 64$ > 15

$9^3 = 729 \Rightarrow 729 \div 9 = 81$ > 17

$10^3 = 1000 \Rightarrow 1000 \div 10 = 100$ > 19

aumento de 2 em 2 ...

Obs:

Mantendo-se esta constante e retrocedendo até o número 1,

$1^3 = 1$, pois $2^3 = 8 \div 2 = 4$

e NÃO $1^3 = 3$ ou 4

$4 - 3 = 1$

Comparando → 3 e 4

4	$8 \div 4 = 2$	3	$8 \div 3 = 2,6$
8		8	
27	$27 \div 4 = 6,75$	27	$27 \div 3 = 9$
64	$64 \div 4 = 16$	64	$64 \div 3 = 21,\overline{3}$
125	$125 \div 4 = 31,25$	125	$125 \div 3 = 41,\overline{6}$
216	$216 \div 4 = 54$	216	$216 \div 3 = 72$
343	$343 \div 4 = 85,75$	343	$343 \div 3 = 114,\overline{3}$
512	$512 \div 4 = 128$	512	$512 \div 3 = 170,\overline{6}$
729	$729 \div 4 = 182,25$	729	$729 \div 3 = 243$
1000	$1000 \div 4 = 250$	1000	$1000 \div 3 = 333,\overline{3}$

estudar com mais profundidade!!!

Prof. Stenio Musich

Pág. 207 - Theorem 3.6.7

<u>Pythagorean theorem</u>

$$a^2 + b^2 = c^2$$

<u>obs:</u> Há a prova no texto.

Pág. 209 - Theorem 3.6.12.

Distance formula for Dimension 2

$P = (x, y)$ and $Q = (x', y')$ is

$$d(P, Q) = \sqrt{(x-x')^2 + (y-y')^2}$$

Pág. 233 - 3.10

The Complex Plane $\mathbb{C}$ is the Euclidean space R^2

$z = a + bi$.

Therefore, a and b are thought of as the coordinates of z as a point of the plane. But any complex numbers is not only a point on the complex plane but also a vector.

$\mathbb{C} \longleftrightarrow R^2$ given by

$$\boxed{a + bi \leftrightarrow \langle a, b \rangle}$$

The algebra of vectors in R^2 applies!

<u>Warning</u>:

In spite of this fundamental correspondence, we will continue to think of complex numbers as numbers (and use the lower case letters).

<u>Obs</u>. Pag. 234 → interesante!!!

Addition of complex numbers:

$(a+bi) + (c+di) = (a+c) + (b+d)i$

$\langle a, b \rangle + \langle c, d \rangle = \langle a+c, \ b+d \rangle$

It corresponds to addition of vectors:

Second, we can easily multiply complex numbers by real ones:

$$(a+bi)\,c = (ac) + (bc)\,i,$$

$$\langle a, b\rangle\, c = \langle ac, bc\rangle.$$

It corresponds to <u>scalar multiplication of vectors</u>.

<u>Warning!</u>
Vector algebra of R^2 is complex algebra, but not vice versa. Complex multiplication is what makes it different.

d) GCTprint.pdf
Pág 155 (165) - Parallax.

The angle p is called the parallax, and in a Euclidean universe p determines the star's distance from the sun, D, by the equation

$$D = d / \tan(p), \text{ where}$$

d is the Earth's distance from the Sun.

We way determine p by observation and d is the radius of Earth's orbit around the Sun
(d is about 8.3 light-minutes).
In practice, p is quite small, so a working formula is $\boxed{D = \frac{d}{p}}$.

The first accurate measurement of parallax was recorded in 1837 by Friedrich Bessel (1784-1846). He found the stellar parallax of <u>0.3 arc seconds</u>.
(1 arc second = 1/3600°)
For star 61 Cygni which put the star at about 10.5 light-years away.

Important:

If we live in a hyperbolic universe with curvature $\underline{k}$, a detected parallax puts a bound (colock um limite) on how curved the universe can be

Consider Fig. 7.3.5, p. 156 (166).

As before, e_1 and e_2 represent the position of the Earth at opposite points of its orbit, so that the distance between them is $\underline{2d}$, or about 16.6 light-minutes.

Assume star $\underline{s}$ is on the

positive real axis

and we have detected a parallax p, so that angle $\angle e_2 s e_1 = 2p$.

Figure 7.3.5 – A detected parallax in a hyperbolic universe puts a bound on its curvature.

The angle $\alpha = \angle e_1 e_2 s$ in Figure 7.3.5, p. 156(166) is less than the angle of <u>parallelism</u>

$$\theta = \angle e_1 e_2 u.$$

Nothing that $\tan(x)$ is an increasing function and applying Lobatchevsky's formula it follows that

$$\tan(\alpha/2) < \tan(\theta/2) = e^{-\sqrt{|K|}\,2d}.$$

We may solve this inequality for $|K|$:

$$\tan(\alpha/2) < e^{-\sqrt{|K|}\,2d}$$

$$\ln(\tan(\alpha/2)) < -\sqrt{|K|}\,2d$$

$\ln(x)$ is increasing

$$\left[\frac{\ln(\tan(\alpha/2))}{2d}\right]^2 > |K|.$$

x^2 is decreasing for $x<0$.

To get a bound for $|K|$ in terms of ρ, note that $\alpha \approx \pi/2 - 2\rho$ (the

triangles used in stellar parallax have no detectable angular deviation from 180°), so

$$|K| < \left[\frac{\ln(\tan(\pi/4-p))}{2d}\right]^2.$$

We remark that for values of p near 0, the repression $\ln(\tan(\pi/4-p))$ has linear approximation equal to $-2p$, so a waiting for K, which appeared in Schwarzschild's 1900 paper [27], is $|K| < (p/d)^2$.

Pág. 179 (189) - 7.6

Geometry of Surfaces

We have seen that any surface is homeomorphic to a polygonal surface representing $\mathbb{T}_g$ or $\mathbb{C}_g$, for some g, and we now show that each of these may be given a homogeneous, isotropic and metric geometry (so that it has constant curvature).

A polygonal surface can only run into trouble homogeneity-wise where the corners come together.

The Minkowskian Metric, Lorentz-Transformation

Pág. 121 (138) -

$$K^{\mu} = (-k_0, k_i) \qquad (4.3.6)$$

Fig. 4.1 Surfaces of constant phase, light rays and wave vectors.

Pág. 122 (139) - Metric Property 1

Light-rays are curves of zero length (null-curves). In Minkowskian coordinates this simply means that

$$0 = ds^2 = -c^2 dt^2 + dx^2,$$

i.e. the speed of light c takes a constant value in every Minkowskian coordinate system.

Pág. 123 (140) – to the Pythagorean theorem we now get

$$L^2 + \left(\frac{v\,\Delta t}{2}\right)^2 = \left(\frac{c\,\Delta t}{2}\right)^2$$

from which we are

$$\Delta t = \frac{\Delta \tau}{\sqrt{1 - v^2/c^2}} \qquad (4.3.9)$$

In words: a moving clock appears to go slower.

1) Methods of Modern Mathematical Physics...pdf

Pág. 03 (17) – 1.2

Metric and normed linear spaces

We will be dealing with sets of functions or operators or other objects and we will offer a way of measuring the distance between the objects in the sets. It is reasonable to define a <u>notion of distance</u> that has the <u>most important</u> properties of ordinary distance in $\mathbb{R}^3$.

Definition - A metric space is a set M and a real-valued function $d(\cdot,\cdot)$ on $M \times M$ which satisfies:

(i) $d(x, y) \geq 0$
(ii) $d(x, y) = 0$ if and only if $x = y$
(iii) $d(x, y) = d(y, x)$
(iv) $d(x, z) \leq d(x, y) + d(y, z)$
[triangle inequality]

Obs.: Triangle inequality, in Euclidean geometry, theorem that the sum of any two (trois de cores ta) sides of a triangle is greater than or equal to the third side, in symbols,

$a + b \geq c$. In essence, the theorem states that the shortest distance between two points is a <u>straight line</u>.

The function d is called a metric on M.

Distance:

$$d(x,y) = \sqrt{(x_1-y_1)^2 + \dots + (x_n-y_n)^2}$$

Example:

Let M be the unit circle in $\mathbb{R}^2$, that is, the set of all pairs of real numbers $\langle \alpha, \beta \rangle$ with $\alpha^2 + \beta^2 = 1$, and let

$$d_1(\langle \alpha, \beta \rangle, \langle \alpha', \beta' \rangle) = \sqrt{(\alpha-\alpha')^2 + (\beta-\beta')^2}$$

Another possible metric is $d_2[p, p'] =$ arc length between the points p, p'

Breve observações:

$$\operatorname{sen}\theta = \frac{CO}{H}$$

$$\cos\theta = \frac{CA}{H}$$

$$\tan\theta = \frac{CO}{CA} = \frac{\operatorname{sen}\theta}{\cos\theta}$$

Pág. 03 (13) - 2.1.1 - Time and Space
Pág. 04 (14) - Fig. 2.1

Fig. 2.1 · Cartesian (left) and spherical (right) coordinates of a point P.

Cartesian and spherical coordinates are related by

$$x = r \sin\theta \cos\varphi$$
$$y = r \sin\theta \sin\varphi$$
$$z = r \cos\theta$$

<u>Notation</u>: Abstract notation

$$(x^i) = (x^1, x^2, x^3)$$

<u>For example:</u>

spherical coordinates,

$x^1 = r$, $x^2 = \theta$, and $x^3 = \varphi$.

<u>Cartesian coordinates</u>:

$$(x^a) = (x, y, z).$$

Pág. 05 (15) – 2.1.2 <u>METRIC</u>:

$$\boxed{r^2 = x^2 + y^2 + z^2}$$

→ That is to say the <u>Pythagorean theorem of Euclidean geometry</u>.

d_{AB} = distance between two points A, B.
(Cartesian coordinates)

$$d_{AB}^2 = (X_B - X_A)^2 + (Y_B - Y_A)^2 + (Z_B - Z_A)^2 \quad (2.4)$$

$$= \sum_{a=1}^{3} \sum_{b=1}^{3} \delta_{ab} (X_B^a - X_A^a)(X_B^b - X_A^b) \quad (2.5)$$

$$\equiv \delta_{ab} (X_B^a - X_A^a)(X_B^b - X_A^b) \quad (2.6)$$

[Einstein's notation].

<u>Obs</u>.: where, in Eq (2.5) we introduced the <u>Kronecker symbol</u>

$$\delta_{ab} \equiv \begin{cases} 1 & \text{if } a = b \\ 0 & \text{if } a \neq b \end{cases} \quad (2.7)$$

and, in Eq (2.6) we used <u>Einstein's convention for the summation over repeated indices</u>.

EUCLIDEAN METRIC

for non-Cartesian coordinates, one cannot directly use the expression (2.4) to calculate d_{AB}. For example, with spherical coordinates

$$d_{AB}^2 \neq (r_B - r_A)^2 + (\theta_B - \theta_A)^2 + (\varphi_B - \varphi_A)^2; \quad (2.8)$$

the above expression is even dimensionally incorrect.

<u>Distance</u> P, P' (Cartesian coordinates)

$$X_P^a \text{ and } X_{P'}^a = X_P^a + dX^a.$$

then, applying Eq. (2.6), we have

$$d_{PP'}^2 \equiv dl^2 = \delta_{ab}\, dX^a dX^b \qquad (2.9)$$

<u>obs</u>: (X^a) and (x^i) describe the same space, they are related by three functions f^a such that $X^a = f^a(x^i)$.

<u>Example</u>:
If (x^i) denote spherical coordinates, you have derived these functions in Exercise 1:

$$f^1(r,\theta,\varphi) = r\sin\theta\cos\varphi,$$

$$f^2(r,\theta,\varphi) = r\sin\theta\cos\varphi,$$

no exercício é <u>sin</u>

$$f^3(r,\theta,\varphi) = r\cos\theta$$

...

Pág. 06(16) - symmetric matrix, is called the <u>METRIC TENSOR</u>.

→

IMPORTANT:

The metric is a machine which transforms coordinates into distances.

CURVILINEAR DISTANCE

Fig. 2.2 (LEFT)

Parametrised curve between A and B.

(RIGHT)

Angles and distances.

(LEFT) → This curve can be parametrised by three functions $x^i(\lambda)$, where

λ is an arbitrary parameter which allows one to move along the curve, assumed to be strictly increasing from λ_A to λ_B on the way from A to B. →

The length of the curve is obtained by summing the lengths of every infinitesimal step from A to B, that is

$$\ell_{AB} = \int_A^B d\ell = \int_A^B \sqrt{e_{ij}\, dx^i dx^j} =$$

$$\int_{\lambda_A}^{\lambda_B} \sqrt{e_{ij} \frac{dx^i}{d\lambda} \frac{dx^j}{d\lambda}}\, d\lambda \quad (2.14).$$

curve → is called a geodesic.
In Euclidean geometry and in the absence of constraints, it is simply a straight line; on the surface of a sphere, it is a great circle.

Pág. 39(49) - 3.1.2

Minkowski Metric and Four-Vectors

$$(x^\mu) \equiv (x^0, x^1, x^2, x^3).$$

$$X^\alpha \longrightarrow x^\mu$$
$$X^\alpha + dX^\alpha \longrightarrow x^\mu + dx^\mu.$$

The space-time interval between those events can then be written as →

$$\boxed{ds^2 = \eta_{\alpha\beta}\, dX^\alpha dX^\beta \equiv f_{\mu\nu}\, dx^\mu dx^\nu,} \quad (3.6)$$

where we introduced the

<u>MINKOWSKI METRIC f</u> (flat),

with components

$$f_{\mu\nu} = \eta_{\alpha\beta} \frac{\partial X^\alpha}{\partial x^\mu} \frac{\partial X^\beta}{\partial x^\nu} \quad (3.7)$$

in arbitrary coordinates (x^μ), which can be seen as a <u>four-dimensional extension of the Euclidean metric.</u>

Pág. 40 (50) Exercise 1

Consider the transformation

$$(X^\alpha) \to (x^\mu) = (ct, r, \theta, \varphi),$$

$$T = t \quad (3.8)$$

$$X = r \sin\theta \cos(\varphi - \Omega t) \quad (3.9)$$

$$Y = r \sin\theta \sin(\varphi - \Omega t) \quad (3.10)$$

$$Z = r \cos\theta$$

where Ω is a constant

Pág. 141(154) — Explanation 3.3
Path of light in a gravitational field.

Fig. E 3.3 →

Path of light passing A to B in a gravitational field (the broken line is the new path with variation δ).

According to Fermat's principle, the path of light passing from A to B, as shown in Fig. 3.3, is the path that requires the minimum time to navigate.

This path is given by the light path decided by the solution of the

EULER EQUATION

derived from the variational principle minimizing the sum of time

$d\sigma / W$

for the propagating spatial segment $d\sigma$.

Because the Euler equation contains the gradient of the gravitational scalar potential the light path depends on gravitation, that is,

though (no entanto) the light path is a linear line when there is no gravitation, when there is gravitation, the light path is not a linear but results in the

"phenomenon of bending of light due to gravitation".

Einstein expressed the bending angle of light passing near the SUN as

$4kM/(c^2 r_m)$, where

K is the universal gravitational constant,

M is the mass of the SUN,

c is the velocity of light, and

r_m is the radius of the SUN.

Obs.: From this, he predicted that the bending angle is 1.7"

(Møller, Nagata & Ito, 1959).

Pág. 308 (326) – 117.

Propagation of light in a static gravitational field. Fermat's principle.

Pag. 309 (327) –

According to (17) this term is equal to $(1/u^4)\mathfrak{G}$, where $\mathfrak{G}$ is the gravitational force on a unit mass, thus the light ray will be

STRAIGHTEST LINE

only if the gravitational force K is zero.

Fermat's principle of least time thus holds in every static gravitational field.

Pág. 312 (328) – 310 (328)

Chapter XI – the Fundamental Laws of Gravitation in the General theory of Relativity.

The most important problem in gravitational theory, which consists in finding the general equations determining the gravitational field variables (γ_{ik}, γ_i, X) or the g_{ik} from a given distribution of masses.

↳ Einstein in 1915 - solution

In Newton's theory of gravitation, the corresponding problem may be stated in the form of Poisson's equation

$$\Delta \chi = 4\pi K \mu \qquad (1)$$

where $K = 6.664 \times 10^{-8}\ cm^3\ gm^{-1}\ sec^{-2}$ (2) is the gravitational constant.

This equation enables us to calculate the gravitational potential χ when the mass density μ is given as a function of the space coordinates.

Chapter 11 – Møller Scattering

Enviei um email para o
Dr. Axel Pelster
axel.pelster@physik.uni-kl.de
com os seguintes dizeres:

"I am an independent researcher and I found your publication: "Möller Scattering", copy attached. I am currently study Møller,

but specifically in the theory of Relativity and I found your publication very interesting, in particular, the geometry of the elastic Møller scattering in the center of mass (V11 - pp. 250 (09) - Fig. 11.2)
L4(2o)

should be represented differently, because the momenta of electrons are slightly different.

Picture 11.2

Analyzing the two Mandelstam variables (11.12 & 40) I think that there is an inaccuracy and the analysis that results from the dependence on both the scattering energy E and the scattering angle θ also.

Sorry there are any inaccuracies as I study your area to provide input in my research.

Pág. 300 (302) - In view of the incompatibility of

Newton's law with the observed uniform distribution of matter, Neumann and Seeliger in 1896 suggested a slight modification of the law ~~the~~ of gravitation, which would have for effect to render a uniform distribution possible.

The equivalent of

POISSON'S EQUATION

when the Neumann-Seeliger law is used, is

$$\Delta \phi - \lambda \phi = 4\pi k \mu,$$

where λ is a positive constant, which may be as small as we choose.

Assuming the density μ to be constant, this modified law, contrary to Poisson's, is compatible with the constancy of the potential, and so is compatible with a

Perihelion and Periastron Precession

Classical calculations of gravitational light bending and time delay become relatively easy once we have established a special relativistic explanation, as relativistic energy equations for systems without rest

mass (and, therefore, without kinematics) are specifically designed to coincide with classical ones.

Relativistic correction for planetary and pulsar orbits is one of the most significant results derived from the

SCHWARZSCHILD solution

(only a special relativistic correction to classical gravity).

π lies between $\frac{223}{71}$ and $\frac{22}{7}$

∴ In the Quadrature of the Parabola, which contains 24 propositions it is show that the area of a parabolic segment is $\frac{4}{3}$ that of the inscribe triangle having the same base and having its opposite vertex at the point where the tangent is parallel to the base.

The summation of a convergent geometric series is involved.

∴ One Arabian writer claims that Archimedes was the discoverer of the celebrated formula

$\Rightarrow$ ~~$K = \sqrt{s(s-a)}$~~ $\boxed{K = \sqrt{s(s-a)(s-b)(s-c)}}$

for the area of a triangle in terms of its three sides. This formula is found in a letter work of Heron of Alexandria.

Pág. 64 (86) - 2.3.2

Menelau's Theorem. A necessary and sufficient condition for three menelaus points D, E, F for the sides BC, CA, AB of an ordinary triangle ABC to be collinear is that

$$(\overline{BD}/\overline{DC})(\overline{CE}/\overline{EA})(\overline{AF}/\overline{FB}) = -1.$$

Necessity. Suppose (see Figure 2.3a) D, E, F are collinear on a line l

obs.:
AEC = 3 points (Pappus's Theorem)
Figure 2.3a
FED = 3 points.
AFB = 3 points.
BCD = 3 points.

which is not the line at infinity. Drop perpendiculars p, q, r on l from A, B, C. Then, disregarding signs,

$$BD/DC = q/r, \quad CE/EA = r/p,$$

$$AF/FB = p/q.$$

$\Rightarrow$

It follows that

$$(\overline{BD}/\overline{DC})(\overline{CE}/\overline{EA})(\overline{AF}/\overline{FB}) = \pm 1.$$

Since (um vez que), however (porém), ℓ must cut one or all three sides externally, we see that we can have only the $-$ sign.

If ℓ is the line at infinity, the proof is simple.

Sufficiency. Suppose

$$(\overline{BD}/\overline{DC})(\overline{CE}/\overline{EA})(\overline{AF}/\overline{FB}) = -1$$

and let EF cut BC in D'. Then D' is a <u>Menelaus point</u> and, by the above (por cima)

$$(\overline{BD'}/\overline{D'C})(\overline{CE}/\overline{EA})(\overline{AF}/\overline{FB}) = -1.$$

It follows that $\overline{BD}/\overline{DC} = \overline{BD'}/\overline{D'C}$, or that $D \equiv D'$. That is, D, E, F are collinear.

Pág. 49(68) -

many gravitational phenomena (like the bending of light rays near a massive body), usually described in terms of the curved (Riemannian)

structure of space-time, can be treated by considering (in an Euclidean space) the vacuum as a polarizable medium endowed with an effective refraction index (see (3.72)), in which light propagates [16, 29]. → [16] } in fronte. [29]

IMPORTANT:

Pág. 37 (56) – In the case of an isotropic 3D space (i.e.,

$$b_1^2(E) = b_2^2(E) = b_3^2(E) \equiv b^2(E))$$

the corresponding deformed metric is given by (2.14), (2.19) and one gets, for any component of u:

$$u = \frac{b_0(E)}{b(E)} c. \qquad (3.70)$$

Ff.: Complemento (2.14) ✓

Pág. 13 (32) – The orthogonality of the coordinates axes is of course expressed by

$$\hat{x}^{\mu}_{SR} \cdot \hat{x}^{\nu}_{SR} = \delta^{\mu\nu} \text{ and}$$

$$\hat{x}^{\mu}_{DSR}(\{\theta\}) * \hat{x}^{\nu}_{DSR}(\{\theta\}) = \delta^{\mu\nu}.$$

It follows by the earlier relation that the unit vectors in the standard Minkowski space M and in the deformed one $\tilde{M}(\{\theta\})$ are proportional, and therefore they specify the same directions in either space (quelquer spaço) (this is due of the

<u>METRIC TENSOR</u>,

while destroying its <u>isochrony</u> and <u>spatial isotropy</u>.

However, since coordinate unit vector is rescaled by <u>a different coefficient in the metric deformation</u>, vectors with the same components in the spaces M and $\tilde{M}(\{\theta\})$ <u>are not parallel to each other</u>.

...

Pág. 14(33) – equation (2.14)

Isotropic 3D Space

$$b_1^2(\{\theta\}) = b_2^2(\{\theta\}) = b_3^2(\{\theta\}) \equiv b^2(\{\theta\}), \quad (2.13)$$

Corresponding deformed metric ~~field~~ reads:

$$\delta_{\mu\nu}[\delta_{\mu 0} b^2(\{\theta\}) - (\delta_{\mu 1} + \delta_{\mu 1} + \delta_{\mu 1}) b^2(\{\theta\})]. \quad (214)$$

...

pág. 15(34)

Therefore, the energy-dependent deformation of the MINKOWSKI METRIC implements a generalization of the concept of geometrization of an interaction (in accordance with Einstein's principle).

The GR theory implements a geometrization (at a global scale) of the gravitational ~~intera~~ interaction, based on its derivability from a potential and on the equivalence between the inertial mass of a body and its

"gravitational charge".

Obs: Esta página aborda:
- gravitational,
- electromagnetic,
- strong
- weak.

Pág. 16 (35) - (2.19) equation

1. A space $\tilde{M}$ spatially isotropic:

$$b_1(E) = b_2(E) = b_3(E) = b(E) \quad (2.19)$$

2. A space $\tilde{M}$ locally conform with the MINKOWSKI space M:

$$b_0(E) = b_1(E) = b_2(E) = b_3(E) = b(E) \quad (2.20)$$

This is a particular case of the

MIRON-TAVAKOL METRIC [13]

which satisfies the

Ehlers-Pirani-Schild axiomatics.

Pág. 06(18) - 6 - The Line Element.

We know that the geometry on the surface of a sphere is Riemannian.
Consider a point P on the surface of a sphere of unit radius (Figure 1a). Its position is given by two polar coordinates (θ, φ), θ being the colatitude ($\angle NOP$) and φ the longitude ($\varphi = \angle XUP$).

Obs.: COLATITUDE →

A colatitude é utilizada em

astronomia porque se refere à distância zenital dos polos celestes.

↳ Sistema de Coordenadas Celestes.

Uma coordenada mede a posição do astro nesse círculo máximo, e a segunda, perpendicular mede a distância do astro a esse plano.

Paralaxe — a posição de uma estrela é medida 2 vezes em momentos diferentes, pois a Terra está em outra posição. Desta forma, através da observação da estrela nas posições A e B, os astrônomos são capazes de medir o ângulo e com isto, determinado a distância da estrela com o uso deste ângulo e a trigonometria.

Paralaxe Heliocêntrica ou anual → é definida com a diferença de posição de uma estrela com vista da Terra e do Sol. Como não podemos ver a estrela do Sol, a observação é feita entre dois pontos opostos da órbita da Terra e o resultado dividido por 2 (dois).

O parsec é a distância para a qual a paralaxe anual é de um segundo de arco ou arcsec. Uma parsec é

igual a 3,26 anos-luz.

Para cálculo do Parsec utilizamos a translação da Terra em volta do Sol, cujo raio é de 1 AU (Unidade Astronômica).

Portanto, um parsec é a distância do Sol a um objeto astronômico que tem um ângulo de paralaxe de um segundo de arco.

Em agosto de 2015, a IAU (União Astronômica Internacional) aprovou a resolução B2 que, como parte da definição de uma escala de

MAGNITUDE BOLOMÉTRICA ABSOLUTA

e aparentemente padronizada, mencionou uma definição explícita existente do parsec como sendo exatamente

$$\boxed{\frac{648000}{\pi}\ \text{au}}$$

, ou aproximadamente

$3.085677581491\,3673 \times 10^{16}$ metros (com base na definição exata do SI da IAU de 2012 da unidade astronômica).

Calculando o valor de um parsec

1 au = 149 597 870 700 m
(relativamente pela definição de 2012 do au)

Definição de 2015:

1 au de comprimento de arco subtende um ângulo de 1" no centro do círculo de raio de 1 pc.
Ou seja, $1\ pc = \frac{au}{\tan(1'')} \cong$
206,264.8 au por definição.(9)

(9) Source:

Books-013-2022/20220629/
To the Sun and Beyond/
s41567-019-0685-3.pdf
→ 1 page
Copy: ARQ/GGB-Geogebra-2022/
20220629/
To the Sun and Beyond/

Conversão de unidades de graus/minuto/segundo em radianos,

$$\frac{1\ pc}{1\ au} = \frac{180 \times 60 \times 60}{\pi},\ e$$

1 au = 149597480 000 m
(def. de 2012)

Portanto,

$\pi pc = 180 \times 60 \times 60$ au =

$180 \times 60 \times 60 \times 149597870700 =$

96 939 420 213 600 000 m
(exatamente pela definição de 2015)

Portanto,

$$1\,pc = \frac{96939420213600000}{\pi}$$

$\cong$ 30 856 775 814 913 673 m
(para o metro mais próximo)

Aproximadamente,

S representa o Sol
E a Terra em um ponto de sua órbita
ES = 1 AU

→

O ângulo SDE é de um segundo de arco ($\frac{1}{3600}$ de um grau), então, por definição, D é um ponto no espaço a uma distância de um parsec do Sol.

Por meio da trigonometria, a distância SD é calculada da seguinte forma:

$$SD = \frac{ES}{\tan 1''}$$

$$SD \approx \frac{ES}{1''} = \frac{1\ au}{\frac{1}{60 \times 60} \times \frac{\pi}{180}} = \frac{648000}{\pi}\ au$$

$$\approx 206241.81\ au.$$

<u>obs.</u>: $1\ pc \approx 3.261563777\ ly$
(light-years)

Um corolário afirma que um parsec é também a distância a partir da qual um disco de uma unidade astronômica de diâmetro (perto do raio) (→ conforme desenho anterior) deve ser visto para ter um <u>diâmetro angular</u> de um segundo de arco.

Matematicamente, para calcular a distância, dada as medidas angulares

obtidas a partir de instrumentos em segundos de arco, a fórmula seria:

$$\text{Distância}_{\text{estrela}} = \frac{\text{Distância}_{\text{Terra-Sol}}}{\tan \frac{\theta}{3600}}$$

θ é o ângulo medido em segundos de arco.
Distância Terra-Sol é uma constante (1 au ou 1.5813×10^{-5} ly).

A distância estelar calculada estará na mesma unidade de medida usada em Distância Terra-Sol.

<u>Obs</u>: Parsec $\frac{648000}{\pi}$ au

Este valor difere da definição clássica de tangente inversa em cerca de 200 km, ou seja somente após o <u>11º algarismo significativo</u>.

<u>Complementando</u>:

Magnitude Absoluta – Magnitude Bolométrica

⟹

Magnitude Absoluta →

é a medida de brilho intrínseco de um objeto celeste.

É a magnitude aparente hipotética do objeto a uma distância padrão de exatamente 10 parsecs (32,6 anos-luz) do observador, assumindo-se nenhuma extinção astronômica da luz da estrela.

Magnitude Bolométrica →

Mbol leva em consideração a radiação eletromagnética em todos os comprimentos de ondas.

Voltando: COLATITUDE

A colatitude é utilizada em astronomia porque se refere à distância zenital dos polos celestes.

Por exemplo, para um observador localizado sobre a Terra em um ponto de latitude 42°N, o arco esférico entre a estrela Polar (aproximadamente situada sobre o polo Norte celeste) e o Zênite (ponto imaginário acima da cabeça do observador) é de

$$90 - 42 = 48°$$

Projetando-se o zênute (zênite) do observador sobre a esfera celeste, a sua colatitude é de 48°.

Adicionando a declinação de uma estrela

Def.: declinação (δ) de um astro é o arco do meridiano do astro compreendido entre o plano do equador celeste e o astro.
→ latitude.

Adicionando a declinação de uma estrela à colatitude do observador obtém-se a máxima latitude desta estrela
(seu ângulo do horizonte a culminação ou trânsito superior)
Por exemplo, se Alfa Centauri é vista com uma latitude de 72° norte (108° Sul) e sua declinação é conhecida (60° S), então pode-se determinar que a colatitude do observador é

$$108 - 60 = 48$$

(i.e. sua latitude é $90 - 48 = 42°$ S

IMPORT: Usar bending of light rays.

geometry on the surface of a sphere is Riemannian.

Consider a point P on the surface of a sphere of unit radius. Its position is given by two angular coordinates (θ, φ),

θ being the colatitude ($\angle NOP$) and φ the longitude ($\varphi = \angle XUP$).

If θ is constant and φ varies from 0 to 2π, the point P moves along the small circle of radius $\sin\theta$.

If φ is constant and θ varies from from 0 to π ($90°$),

the point P moves along the meridiano large circle NPS.

Fig. 1b

If $Q(\theta + d\theta, \varphi + d\varphi)$ is a neighbouring point on the sphere at an infinitesimal distance from P (Figure 1b) then

$$ds^2 = d\theta^2 + \sin^2\theta \, d\varphi^2 \qquad (1).$$

It is customary to regard relations like (1) as defining a <u>line element</u>.

Formula (1) is the line element on the surface of a sphere or a <u>line element of a two-dimensional Riemannian space</u>.

If however, we were considering two neighbouring points on a plane

with coordinates (x, y),

$(x + dx, y + dy)$,

the line element would be

$$\boxed{ds^2 = dx^2 + dy^2.} \qquad (2)$$

↳ Equation (2) is a line element of a two-dimensional Euclidean space.

Pág. 08 (20) – Riemannian spacetime

$(x^1 + dx^1, x^2 + dx^2, x^3 + dx^3, x^4 + dx^4)$

We take the line element as a quadratic in dx^1, dx^2, dx^3, dx^4.

$$ds^2 = g_{11}(dx^1)^2 + 2g_{12}(dx^1)(dx^2) + 2g_{13}(dx^1)(dx^3) + 2g_{14}(dx^1)(dx^4) + g_{22}(dx^2)^2 + 2g_{23}(dx^2)(dx^3) + 2g_{24}(dx^2)(dx^4) + g_{33}(dx^3)^2 + 2g_{34}(dx^3)(dx^4) + g_{44}(dx^4)^2$$

or we may write it as

⇒

$$ds^2 = \sum_{i=1}^{4} \sum_{k=1}^{4} g_{ik}\, dx^i dx^k,$$

where

g_{ik} are 10 functions of "position", i.e. of the four variables x^1, x^2, x^3, x^4, <u>symmetric</u> in i and k, $g_{ik} = g_{ki}$.

Verdade Matemática.

As afirmações matemáticas que sabemos demonstrar serem verdade recebem o nome de teorema.

São verdades incondicionais e eternas.

Importante: Trata-se de uma prerrogativa existente somente na matemática.

Verdade: (?) → até agora.

Dada uma circunferência qualquer, a razão entre o seu perímetro e o seu diâmetro é π.

Matemática → Circunferência Ideal (abstrato)

Circunferência é um objeto matemática

Os teoremas sobre circunferências valem para a circunferência matemática que é bem definida.

Definição: Uma circunferência de centro P e raio r é o conjunto de pontos que distam r do ponto P.

P ⟵⟶ A (ideal)

P ⟵⟶ A (real)

↑

MUS

A circunferência matemática é perfeita (e abstrata).

Definições:

Em uma nova teoria defina todos os termos que você irá utilizar.
(importante)

Todo número inteiro par, maior ou igual a 4, é a soma de dois números primos.

Conjunto dos números naturais (ou inteiros não-negativos)

$\mathbb{N} = \{0, 1, 2, 3, \ldots\}$

↳ é um número natural

0 é divisor de algum número inteiro?

Segundo a definição para que 0 divida um inteiro b é preciso existir um número inteiro x tal que $0 \cdot x = b$.

↳ tem que ser 0 (zero)

Obs.:

x pode ser qualquer inteiro.

0 é divisor de 0 e também é verdade que o único inteiro que 0 divide é ele próprio.

Outras definições:

Definição 2 → Um inteiro a é par se $2 | a$.

Definição 3 → Um inteiro a é ímpar se existe um inteiro k tal que

$a = 2 \cdot k + 1$.

Definição 4 → Um inteiro p é primo se $p > 1$ e se os únicos divisores positivos de p são 1 e p.

Obs.: 1 não é primo.

Afirmações:

- A soma de dois inteiros pares é um inteiro par.

- Se o produto de dois inteiros a e b for par, então a é par ou b é par.
  ↳ pode ser um número ou os dois.

F Se a e b são inteiros tais que a/b e b/a então a = b. (transitiva)
↳ Falsa. Prova da falsidade: a = 2 e b = -2.

- Todo número inteiro par, maior ou igual a 4, é a soma de dois números primos.

Obs. Foi testado por computador até

$$n \leq 4 \cdot 10^{18}.$$

Todos os inteiros pares entre 4 e $4 \cdot 10^{18}$ eram somas de dois primos.

Na verdade, não se sabe se é verdadeira ou falsa.
→ conjectura.

A soma de dois inteiros pares é um inteiro par → é um teorema (afirmação verdadeira).

Se o produto de dois inteiros a e b for par, então a é par ou b é par.
→ é um teorema (afirmação verdadeira).

Todo número inteiro par, maior ou igual a 4, é a soma de dois números primos
→ é uma conjectura, conhecida como <u>Conjectura de Goldbach</u> (1742).

Euclides (300 A.C.) fez uma demonstração de que existem <u>infinitos números primos</u>.
Considerada um belo exemplo de raciocínio lógico.

$$MUS(\pi) = \pi \cdot G_L \cdot G_U$$

π ↓ matemático (conceito)

$G_L \cdot G_U$ → bending of the light → real.

<u>Obs</u>: <u>Importantíssimo!!!</u>

"G_L" = Gravidade Local (Terra)

"G_U" = Gravidade do Universo (Universo)

$$MUS(\pi) = \pi \cdot GL \cdot GU$$

π → Conceito matemático

GL → Gravidade local

GU → Gravidade Universo.

<u>Three Fundamental Forces</u>

1) Electromagnetism
2) Strong Nuclear Force
3) Weak Nuclear Force

$$GL = \underbrace{E + SNF + WNF}_{\text{Bending of light}}$$

$$GU = \text{Gauss's Curvature}_{(\text{Universe})} \; (E + SNF + WNF)$$

<u>Obs</u>: GL and GU → ~~st~~ efeitos das 3 forças fundamentais.

<u>Important</u>: π é uma constante fixa estipulada por cálculos

matemáticos que demonstrem que este coeficiente não seja transcendental.

Ex.:

3,14

Podendo ser:

$3,13 \leq x \leq 3,14$

Obs.:

Certo dizer que o valor é menor que 3,14, pois temos os outros fatores como

GL e GU como elementos, fatores que alteram o π conceitual.

$3,14 \cdot 0,\ldots \cdot 0,\ldots =$

o resultado é obviamente menor.

Portanto: Teremos

$\pi_L = \pi \cdot GL$

$\pi_U = \pi \cdot GL \cdot GU$

GU interfere também GL (local)

ou mais precisamente:

$\pi_L = \pi \cdot F_L$ obs.: $F_L = TFF_L$ (Three Fund. Forces)

$\pi_U = \pi \cdot F_L + F_U$ obs.: $F_U = TFF_U$ (Three Fund. Forces Universe)

(F_L)

$F_L = TFF_L = E_L + SNF_L + WNF_L$

$F_U = TFF_U = E_U + SNF_U + WNF_U$

<u>Important</u>:

$\Pi_L = \Pi \cdot F_L \cdot \underbrace{F_U}_{\text{valor menor}}$

$\Pi_U = \Pi \cdot F_L \cdot \underbrace{F_U}_{}$

Valor maior pois abrange o Universo como um todo.
(Gauss's curvature)

Poderíamos dizer que o F_U localmente é pequeno, mas não pode ser desprezado.

<u>Assim</u>:

$$\Pi = \underbrace{\Pi \cdot F_L}_{\text{Local}} \cdot F_U$$

Universal.

$\Pi < \Pi$.

GCTprint.pdf (001---GCTprint.pdf)

Pág. 154 (164) - Figure 7.3.2.

The angle of parallelism θ of a point z to a line L.

Figure 7.3.2.

Observing negative curvature:

Suppose we are located at a point z in a hyperbolic universe with curvature K.
We see in the distance a hyperbolic line L that seems to extend indefinitely.
We might intuitively see the point w (w)

on the line that is closest to us, as suggested in Figure 7.3.2, p. 154.

Now suppose we look down the road a bit to a point v.

If v is close to w the angle $\angle wzv$ will be close to 0.

As v gets further and further away from w, the angle will grow, getting closer and closer to the angle $\theta = \angle wzu$, where u is an ideal point of the line L.

→ A curious fact about hyperbolic geometry is that this angle θ, which is called the <u>angle of parallelism of z to L</u>, is a function of z's distance d to L.

<u>Obs.</u>: In Section 5.4 we saw that $\cosh(d) = 1/\sin\theta$ in $(\mathbb{D}, \mathcal{H})$.

Section 5.4 – Area and Triangle Trigonometry

→ Pág. 100 (110)

<u>Análise</u>: Pág. 103 (113) →

Theorem 5.4.9

The area of a hyperbolic triangle in $(\mathbb{D}, \mathcal{H})$ having interior angles α, β, and γ is

$$A = \pi - (\alpha + \beta + \gamma).$$

Figure 5.4.10 Determining the area of a hyperbolic triangle.

<u>Obs</u>: <u>IMPORTANT</u>:

A área está errada; pois o <u>π is wrong</u>.

<u>Vejamos</u>: Δpqr

We have extended segment qp to the ideal point t, u is an ideal point of line rq, and v is an ideal point of line pr. The area of the ideal triangle Δtuv is π.

$\hookrightarrow$ wrong!!!

(continuando o estudo). $\longrightarrow$

Notice that regions R_1, R_2, and R_3 are all $\frac{2}{3}$-ideal triangles contained within the ideal triangle.

Consider R_1, whose ideal points are u and t, and whose interior angle is $\angle ugt$.

Since the line through q and r has ideal point u, the interior angle of R_1 is

$\angle ugt = \pi - \beta$.

Similarly, R_2 has interior angle $\pi - \alpha$ and

R_3 has interior angle $\pi - \gamma$.

Let R denote the triangle region Δpqr whose area $A(R)$ we want to compute.

<u>Vejamos</u>:

We then have the following relationships among areas:

$$\pi = A(R) + A(R_1) + A(R_2) + A(R_3)$$

$$= A(R) + [\pi - (\pi - \beta)] + [\pi - (\pi - \alpha)] + [\pi - (\pi - \gamma)].$$

Solving for $A(R)$,

$$A(R) = \pi - (\alpha + \beta + \gamma),$$

and this completes the proof.

<u>Voltando</u>:

Pág. 154 (164) –

$$\cosh(d) = 1/\sin(\theta)\sin(\Pi, \mathcal{L}).$$

In particular, one way deduce the <u>distance</u> d to the line L by computing θ.

<u>Obs</u>: In a Euclidean geometry, if one looks farther and farther down (mais para baixo)

the line L, the angle will approach 90° no matter one's distance d from the line.

The following theorem provides another formula relating the angle of parallelism to a point's distance to a line.

Theorem 7.3.3

Lobatchevsky's formula

In hyperbolic geometry with curvature K, the hyperbolic distance d of a point z to a hyperbolic line L is related to the angle of parallelism θ by the formula

$$\tan(\theta/2) = e^{-\sqrt{|K|}\,d}.$$

IMPORTANT:

A prova deste teorema deverá ser adequada à nova geometria baseada III (M.U.S.).

PROOF: For this proof, let

$$s = \frac{1}{\sqrt{|K|}}.$$

Figure 7.3.4 Deriving Lobatchevsky's formula.

Note that s is the Euclidean radius of the circle at infinite (infinite) in the disk model for hyperbolic geometry with curvature K.

Since angles and lines and distances are preserved, assume z is the origin and L is orthogonal to the positive real axis, intersecting it at the point x (with $0 < x < s$).

Recall the half-angle formula

$$\tan(\theta/2) = \frac{\tan(\theta)}{\sec(\theta)+1}.$$

According to Figure 7.3.4, p.154, $\tan(\theta) = \frac{r}{s}$, where r is the Euclidean radius of the circle containing

the hyperbolic line L.

Furthermore, $\sec(\theta) = (x+r)/s$, so

$$\tan(\theta/2) = \frac{r}{x+r+s}. \qquad (1)$$

We may express x and r in terms of the hyperbolic distance d from 0 to x.

In Exercise 7.3.2, we prove the hyperbolic distance from 0 to x in $(\mathbb{D}_K, \mathcal{H}_K)$ is

$$d = s \ln\left(\frac{s+x}{s-x}\right) \text{ so that}$$

$$x = s \cdot \frac{e^{d/s} - 1}{e^{d/s} + 1}.$$

Express r in terms of d by first expressing it in terms of x.

Note that segment $x\,x^*$ is a diameter of the circle containing L, where $x^* = \frac{-1}{\bar{x}}$ is the point symmetric to x with respect to the circle at infinity.

$\Rightarrow$

Thus, r is half the distance from x to x^*:

$$r = \frac{1 + Kx^2}{2Kx}.$$

Replacing K with $-1/s^2$, we have

$$r = \frac{s^2 + x^2}{2x}.$$

One checks that after writing x in terms of d, r is given by

$$r = \frac{2 s e^{d/s}}{e^{2d/s} - 1}.$$

Substitute this expression for r into the equation labelled (1) in this proof, and after, we are

$$\tan(\theta/2) = e^{-d/s}.$$

Since $s = 1/\sqrt{|K|}$ this completes the proof.

<u>INTERESSANTE</u>:

<u>PARALLAX</u> (presta atenção!!!)

e_1 and e_2 denote the Earth's position points of its orbit, and the star S is orthogonal to the plane of the Earth's orbit.

The angle ρ is called the <u>parallax</u>, and in a Euclidean universe, ρ determines the star's distance from the Sun, D, by the equation

$D = d / \tan(\rho)$, where d is the Earth's distance from the Sun.

<u>Obs.</u>: d is about 8.3 light-minutes.

In practice, ρ is quite small, so a working formula is

$$D = \frac{d}{\rho}.$$

The first accurate measurement of parallax was recorded in 1837 by Friedrich Bessel (1784–1846).

He found the stellar parallax of 0.3 arc-seconds (1 arc second = 1/3600°) for star 61 Cygni, which put the star at about 10.5 light-years away.

Interesante:

If we live in a hyperbolic universe with curvature K, a detected parallax puts a bound on how curved the universe can be.

Obs.: $2d \cong 16.6$ light-minutes.

Assume star s is on the positive real axis and we have detected a parallax ρ, so that angle

$$\angle e_2 s e_1 = 2\rho.$$

Figure 7.3.5 A detected parallax in a hyperbolic universe puts a bound on its curvature

$\Rightarrow$

The angle $\alpha = \angle e_1 e_2 s$ in Figure 7.3.5, p. 156 is less than the angle of parallelism

$$\theta = \angle e_1 e_2 u.$$

Noting that $\tan(x)$ is an increasing function and applying <u>Lobatchevsky's formula</u> it follows that

$$\tan(\alpha/2) < \tan(\theta/2) = e^{-\sqrt{|K|2d}}.$$

We may solve this inequality for $|K|$:

<u>off</u>: $e^{\ln x} = x$

$\ln$ = natural logarithm
e = natural exponent
x = real number

$e \cong 2.718281828459\ldots$
(irrational and transcendental number)

$$\tan(\alpha/2) < e^{-\sqrt{|K|2d}}$$

$$\ln(\tan(\alpha/2)) < -\sqrt{|K|2d}$$

$\ln(x)$ is increasing

$$\left[\frac{\ln(\tan(\alpha/2))}{2d}\right]^2 > |K|.$$

x^2 is decreasing for $x < 0$.

To get a bound for $|K|$ in terms of p, note that $\alpha \approx \pi/2 - 2p$ (the triangles used in stellar parallax have no detectable angular deviation from $180°$), so

$$|K| < \left[\frac{\ln(\tan(\pi/4 - p))}{2d}\right]^2.$$

We remark that for values of p near 0, the expression $\ln(\tan(\pi/4 - p))$ has linear approximation equal to $-2p$, so a working bound for K, which appeared in Schwarzschild's 1900 paper [27], is $|K| < (p/d)^2$.

Pág. 158 (168) – 7.4

The Family of Geometries (X_K, G_K)

A strong connection exists between the family $(\mathbb{P}^2_K, S_K)$ of elliptic geometries with curvature $K > 0$ and the family $(\mathbb{D}_K, \mathcal{H}_K)$ of hyperbolic geometries with curvature $K < 0$.

The two families sport identical descriptions of the transformation group, identical descriptions of <u>straight lines</u>, <u>identical arc-length</u> and <u>area formulas</u>, as well as identical formulas for the area of a triangle.

Definition 7.4.1

For each real number K the geometry (X_K, G_K) has space

$$X_K = \begin{cases} \mathbb{D}_K & \text{if } K < 0; \\ \mathbb{C} & \text{if } K = 0; \\ \mathbb{P}^2_K & \text{if } K > 0, \end{cases}$$

and group of transformations G_K

consisting of all Möbius transformations of the form

$$T(z) = e^{i\theta} \frac{z - z_0}{1 + K\bar{z}_0 z},$$

where $\theta \in \mathbb{R}$ and z_0 is a point in X_K. Moreover, the unique line through two points p and q in (X_K, G_K) is the unique circle through the points p, q, and $-1/(K\bar{p})$.

A smooth curve $r : [a, b] \to X_K$ has arc-length given by

$$L(r) = \int_a^b \frac{2|r'(t)|}{1 + K|r(t)|^2}\, dt.$$

The area of a polar region R in (X_K, G_K) is given by

$$A(R) = \iint_R \frac{4r}{(1 + Kr^2)^2}\, dr\, d\theta.$$

Obs: If $K > 0$, the sum of the angles of a triangle must be greater than π; and

If $K < 0$ the sum of the angles

of a triangle must be less than π.

If $K>0$ the space $X_K = P_K^2$ has finite area;

If $K<0$, $X_K = \mathbb{D}_K$ has infinite area.

If $K>0$ the circumference of a circle with radius r is less than $2\pi r$;

if $K<0$ the circumference is greater than $2\pi r$.

<u>Obs</u>: $K=0$

(X_0, g_0) corresponds to Euclidean geometry, though (no intanto) with a scaled metric.

In particular, lines in (X_0, g_0) correspond to Euclidean lines (since $K=0$, $-1/(K\bar{p}) = \infty$, so the unique line through p and q is the Euclidean line) and when $K=0$ the arc-length is simply twice the usual Euclidean arc-length.

So while we are scaling distances in (X_0, G_0), Euclidean geometry applies: triangles are Euclidean triangles and have angle sum equal to $180°$.

Triangles with a right angle are Euclidean right triangles and satisfy the Pythagorean theorem.

We treat (X_K, G_K) as one big family of geometries.

The sign of K dictates the type of geometry we have, and the magnitude of K dictates the radius of the disk in which we model the geometry (unless (a priori) $K=0$ in which case the space is $\mathbb{C}$).

Moreover, Euclidean geometry (X_0, G_0) marks the edge from which we move into a hyperbolic world is K drops below 0, and into an elliptic world if K rises above 0.

We now summarize some results established in the previous section and emphasize key features common to all (X_K, G_K).

Arc-length is an invariant function of (X_K, G_K) and that the arc-length ~~that~~ ensures that the shortest path from p to q in (X_K, G_K) is along the line between them.

We have discussed these facts in the cases $K = -1, 0, 1$, and the result holds for arbitrary K. So the <u>arc-length formula</u> provides a metric on (X_K, G_K):

Given $p, q \in X_K$, we define $d_K(p,q)$ to be the length of the <u>shortest path from p to q</u>.

The circle in (X_K, G_K) centered at p through q consists of all points in X_K whose distance from p equals $d_K(p,q)$.

Pág. 15(27) -

Pág. 14(26) - Even in Euclidean geometry, we did not add two vectors at different points, but we have almost forgotten this

Pág. 15(27) - this disability of ours because, in order to add a vector $\bar{A}$ at P and a vector $\bar{B}$ at Q, we could always replace $\bar{B}$ at Q by a parallel vector at P and then add the two (say, by parallelogram rule).
→

IMPORTANT: In Riemannian Geometry we do not have a parallel vector at P because of the absence (ausencia) of a parallel postulate,

$\Downarrow$

$\Rightarrow$ criar um novo postulado baseado na nova geometria TTT (M.U.S.)

and so we cannot afford to forget this disability.

14. Covariant Derivative of a Contravariant Vector

... We cannot do this because we do not have a parallel postulate which would have enable us to transfer a vector A^a at P to a parallel and equal vector at Q.

Pág. 26(38) – Einstein postulated his law of gravitation as

$$G^{ab} = -K T^{ab}$$

K is a constant and T^{ab} is the matter energy tensor.

Estudar:

On comparing his equations with Newtonian equations of gravity, he found that if the gravitational field is weak enough and if the velocities involved are much smaller compared to the velocity of light, then to that order of approximation, his theory gives the exact Newton Poisson equation, provided

$$\boxed{K = +\frac{8\pi G}{c^2}}$$

thus, if there are strong gravitational fields and if high velocities are involved, one must use the full Einstein equations

$$R^{ab} - \frac{1}{2} g^{ab} R = -\frac{8\pi G}{c^2} T^{ab}.$$

In space devoid of matter (see).

$T^{ab} = 0$ and we get

$$R^{ab} - \frac{1}{2} g^{ab} R = 0; \quad R^{ab} = \frac{1}{2} g^{ab} R,$$

→

$$g_{ab} R^{ab} = \frac{1}{2} g_{ab} g^{ab} R.$$

$R = 2R$ or $R = 0$,

therefore $R^{ab} = 0$.

Einstein's equations of gravitation in empty space satisfy

$$R_{ab} = 0. \quad \underline{(20220813)}$$

Pág. 110 (120) – 4. Killing Vector Fields.

We have mentioned symmetry transformations for a spacetime. Such symmetries are characterized by the existence of the so-calling

<u>Killing vector fields in M.</u>

Pág. 111 (121) – Suppose now that the local one-parameter group of diffeomorphisms ϕ_t generated by a

<u>vector field K is a group of isometries,</u>

i.e. for every t, ϕ_t is an <u>isometry</u>,

$$\phi_t * g_{ab} = g_{ab} \text{ for all } t, \quad (18)$$

then K is called a <u>Killing vector field</u> and we have

$$L_K g = \lim_{t \to 0} \frac{1}{t} [g - (\phi_{-t}) * g] = 0 \quad (19)$$

Thus, the necessary and sufficient condition for K to be a <u>KILLING VECTOR FIELD</u> is that the Lie derivative of g along K vanishes.

Next, since

$$L_K g_{ab} = K_{b;a} + K_{a;b}, \quad (20)$$

for a Killing vector field we get

$$K_{b;a} + K_{a;b} = 0 \quad (21)$$

which is called the <u>KILLING EQUATION</u>.

Pág. 112 (122) - Riemann tensor [8] [24]

(3) Killing vector field in a spacetime

↳ Next, consider the following equation defining <u>the Riemann tensor</u> [8]

→

METRIC $\rightarrow \nabla \nabla$

$$\nabla_a \nabla_b \xi_c - \nabla_b \nabla_a \xi_c = R_{abc}{}^{d} \xi_d \quad (24)$$

If now ξ^a, appearing in the above, is a <u>KILLING VECTOR FIELD</u>, then using the <u>KILLING EQUATION (23)</u> and the symmetries of the Riemann tensor (24), gives

$$\nabla_a \nabla_b \xi_c = -R^{d}{}_{bca} \xi_d \quad (25)$$

$\Rightarrow$ <u>Interessante:</u>

As a consequence of (25) a Killing vector field ξ^a is completely determined by values

ξ^a and $L_{ab} = \nabla_a \xi_b$ at any $p \in M$. this means that given (ξ^a, L_{ab}) at p, the values (ξ^a, L_{ab}) at any other q are determined by integrating the ordinary differential equations (26) $\Rightarrow$

$$v^a \nabla_a \xi_b = v^a L_{ab}, \qquad (26)$$

$$v^a \nabla_a L_{bc} = -R^d{}_{bca}\, \xi_d\, v^a$$

along any curve joining p to q,

where v^a denotes the tangent vector to that curve.

$\Rightarrow$ Lorentz metric with signature -2...

Pág. 297 (305) – 15 – Quantum Field Theory in Curved Spacetime: Canonical Quantization

The Planck dimensions represent scales on which the quantum effects of the gravitational field become important. For a system, say dust confined to a length scale L,

$$A_G \sim \frac{c^4}{16\pi G} \cdot \frac{8\pi G \rho}{c^4} \cdot \frac{4\pi L^3}{3} \cdot \frac{L}{c} = \frac{2\pi \rho L^4 c}{3}.$$

But

$$L > \frac{2G}{c^2}\left(\frac{4\pi L^3 \rho}{3}\right) \Rightarrow \rho L^2 \leq \frac{3c^2}{8\pi G}.$$

Consequently,

$$A_G \leq \frac{2\pi L^2 c}{3} \cdot \frac{3c^2}{8\pi G} = \frac{L^2 c^3}{4G},$$

so that quantum effects of the gravitational field are significant, if

$$\frac{L^2 c^3}{4G} \leq \hbar, \text{ i.e. } L \leq 2L_p.$$

<u>obs</u>: QFT in CST $\rightarrow$ quantum field theory in curved spacetime.

value of the energy momentum tensor for matter, i.e.

$$G_{\mu\nu}(g_{\alpha\beta}) = 8\pi \langle T_{\mu\nu} \rangle \quad (2).$$

There is a problem with the above semi-classical Einstein equation that gives the back reaction of the quantum field on the gravitational field. According the equivalence principle which <u>lied at the foundation of all metric theories of gravity</u>, all <u>forms of matter and energy couple equally to gravity</u>.

Pág. 405 (411) - 19 - The Photon, the Graviton and the Gravitino.

Pág. 407 (413) - 2. The Graviton

The existence of the Graviton field can be seen by carrying out a straightforward flat space expansion of the Einstein-Hilbert Lagrangian density

$$S = \int \mathcal{L}_{E-H}\, d^4x, \quad \mathcal{L}_{E-H} = \sqrt{-g}\, R, \qquad (17)$$

where g is the determinant of the metric tensor $g_{\mu\nu}$ and R is the scalar curvature.

La geometria non-euclidea/
nonEuclideanGeom00bonorich.pdf
→ Non-euclidean geometry —
Roberto Bonola (00B-nonEuclideanGeom00bonorich.pdf)
Pág. 67(83) — §34 —

Gauss defines parallels as follows:
↳ (Source: Gauss Werke, Bd VIII, p. 202-'9).

Fig. 33

If the coplanar straight lines AM, BN do not intersect each other, while,
every straight line through (através) A between AM and AB cuts BN, then AM is said to be parallel to BN [fig. 33].

He supposes a straight line passing through A, to start from the position AB, and then to rotate continuously on the side towards (em direção) which

BN is drawn, till it reaches (até atingir) the position A'C, in BA produced.

This line begins by cutting BN and in the end it does not cut it.

Thus there can be one and only one position, separating the lines which intersect BN from those which do not intersect it.

Gauss's definition (...) only the first of these is said to be parallel to BN.

Analisando GAUSS:

Obs. 1, 2, 3 are parallels

Portanto:

I. He proceeds to show that the parallelism of the line AM to the line BN is independent of the points A and B, provided the sense in which the lines are to be produced indefinitely remains the same.

It is obvious that we would obtain the same parallel AM

Pág. 69 (85)

if we kept A fixed and took instead (em vez de) of B another point B' on the line BN, or on that line produced backwards (para trás).

It remains to prove that if AM is parallel to BN for the point A, ~~or on that line (line)~~ it also the parallel to BN any point upon AM, or upon AM produced backwards.

Instead of (termino da coreta)

Instead of A [Fig. 34] take another starting point A' upon AM. Through A', between A'B and A'M, draw the line A'P in any direction.

(Fig. 34)

Through Q, any point on A'P, between A' and P, draw the line AQ.

Then, from the definition, AQ must cut BN, so that it is clear QP must must also cut BN.

Thus AA'M is the first of the lines which do not cut BN, and A'M is parallel to BN. (clear!!!)

Again take the point A' upon AM produced backwards [Fig. 35]

(Fig. 35)

Draw through A', between A'B and A'M, the line A'P in any direction.

Produce A'P backwards and upon it take any point Q.

Then, by the definition, QA must cut BN, for example,

Pág. 70(86)... cont.

in R. Therefore A'P lies (encontrase) within the closed figure

A'ARB, and must cut one of the four sides

A'A, AR, RB, and BA'.

Obviously this must be the third side RB, and therefore

A'M is parallel to BN.

II. The Reciprocity of the Parallelism can also be established.

In other words, if AM is parallel to BN, then BN is also parallel to AM!

⇒

GAUSS proves this results as follows:

From any point B upon BN draw BA perpendicular to AM.

(Fig. 36)

At B, on the same side of AB as BN, make

$$\measuredangle ABC = 1/2 \measuredangle N'BN.$$

There are two possible cases:

Case (i), when BC cuts AM [cf. Fig. 36].

Case (ii), when BC does not cut AM [cf. Fig. 37].

(Fig. 37)

Volfando: case (i)

Let BC cut AM in D.
Take AE = AD, and join BE.

Make ∡ BDF = ∡ BED.

Since AM is parallel to BN,
DF must cut BN, for example, in G.
From EM cut off EH equal to DG.
Then, in the triangles

BEH and BDG, it follows that

Pág. 71 (87)

∡ EBH = ∡ DBG.

therefore ∡ EBD = ∡ HBG.

But ∡ EBD = ∡ N'BN.

therefore BN' and BH coincide, and
BN' must cut AM.

But BN' is any line through B, between BA and BN.
Therefore BN is parallel to AM.

20220820 III

Case (ii) - In this case let D be any arbitrary point upon AM.

Then with the same argument as above,

$\angle EBD = \angle GBH$.

But $\angle ABD < \angle ABC$.

Therefore $\angle EBD < \angle N'BN$.

Therefore $\angle GBH < \angle N'BN$.

Therefore BN' must cut AM.

But BN' is any line through B, between BA and BN.

Therefore BN is parallel to AM.

Thus in both cases we have proved that if AM is parallel to BN, then BN is parallel to AM. (I)

(I) → Gauss's second proof of this theorem is given in the German translation. However it will be found that in it he assumes that BC cuts AM, and to prove this the argument (argument) used above is necessary.

The next theorem proved by Gauss in this synopsis is as follows:

III. If the line (1) is parallel to the line (2) and to line (3), then (2) and (3) are parallel to each other. (Pág. 72 (88).

Case (i) - Let the line (1) lie between (dentro entre) (2) and (3). [cf. Fig. 38].

(Fig. 38)

Let A and B be two points on (2) and (3), and let AB cut (1) in C.

Through A let an arbitrary line AD be drawn between AB and (2).

Then it must cut (1), and on being produced must also cut (3).

Since this holds for every line such as (tal como) AD, (2) is parallel to (3).

Case (ii) – Let the line (1) be outside both (2) and (3), and let (2) lie between (1) and (3) [cf. Fig. 39].

(Fig. 39)

If (2) is not parallel to (3), through any point chosen at random upon (3), a line different from (3) can be drawn

which is parallel to (2).

This, by Case (i), is also parallel to (1), which is absurd.

This short Note on Parallels closes (closes) with the theorem that if two lines AM and BN are parallel, these lines produced backwards cannot meet.

Pag. 73 (89) – In a second memorandum on parallels, Gauss goes over (passa per cima) the same ground, but adds the idea of CORRESPONDING POINTS on two parallel AA', BB'.

⇒ Two points A, B are said to correspond, when AB makes equal internal angles with the parallels on the same side. (cf. Fig. 40)

(Fig. 40)

With regards to these Corresponding Points he states the following theorems:

(i) If A, B are two corresponding points upon two parallels, and M is the middle point of AB, the line MN,

perpendicular to AB, is parallel to the two given lines, and every point on the same side of MN as A lie nearer A than B.

(ii) - If A, B are two corresponding points upon the parallel (1) and (2), and A', B' two other corresponding points on the same lines, then

$AA' = BB'$, and conversely.

(por outro lado)

(iii) - If A, B, C are three points on the parallels (1), (2) and (3), such that (de tal modo que) A and B, B and C, correspond, then A and C also correspond.

Pag. 74 (90) — The idea of Corresponding Points, when taken in connection with three lines of a pencil (that is, three concurrent lines [cf. Fig. 41]) allows us to define the circle as the locus of the points on the lines of a pencil which correspond to a given point.

Important!!!

(Fig. 41)

But this locus can also be constructed when the lines of the pencil are parallel.

In the Euclidean case the locus is a straight line: but putting aside the Euclidean hypothesis, the locus in question is a line, having many properties in common with the CIRCLE, but yet not itself a circle.

Indeed if any three points (itself) are taken upon it, a circle cannot be drawn through them.

This line can be regarded as the limiting case of a circle, when its radius become infinite.

In the Non-Euclidean geometry of LOBATSCHEWSKY and BOLYAI this locus plays a most important part, and we shall meet it there under the name of the HOROCYCLE (I)

*

Obs.: Horocycle in hyperbolic geometry or limit circle is a curve whose normal or perpendicular geodesics all converge asymptotically in the same direction.

(I) [LOBATSCHEWSKY: Grenzkreis, Courbe-limite or Horicycle.

BOLYAI: Parazykl, h-line.

→ TROPE (discussion of the properties of this curve)

This work GAUSS did not need to complete, for in 1832 he received from Wolfgang Bolyai a copy of the work of his son Johann on Absolute Geometry. (A)

off: Absolute Geometry - Bolyai.

other book: ISBN 978-613-5-77145-9

obs.: Absolute geometry is a geometry based on an axiom system that does not assume the parallel postulate or any of its alternatives.

The term was introduced by János Bolyai in 1832. It is sometimes referred to as neutral geometry, as it is neutral with respect to the parallel postulate. The theorems of absolute geometry hold in some non-Euclidean geometries, such as hyperbolic geometry, as well as in Euclidean geometry. Absolute geometry is an extension of ordered geometry, and thus,

all theorems in ordered geometry hold in absolute geometry.

The converse is not true.

Absolute geometry assumes the first four of Euclid's Axioms, to be contrasted with affine geometry, which assume Euclid's first, second, and fifth (parallel postulate) axioms.

Ordered geometry is a common foundations of both absolute and affine geometry.

HOROCYCLE (*) (A)

Pág. 74(90) – From letters before and after the date at which he interrupted his work, we know that GAUSS has discovered in his geometry an

ABSOLUTE UNIT OF LENGTH

[cf. LAMBERT and LEGENDRE],

and that a constant K appeared in his formulae, by means of which all the problems of the Non-Euclidean Geometry could be solved [letter to Taurinus,

Nov 8, 1824].

Speaking more fully of these matter in 1831 [letter to Schumacher],

Pag. 75 (90) —

he gave the length of the circumference of a circle of radius r in the form

$$\pi k \left(\frac{r}{e^k - e} - \frac{r}{k} \right).$$

With regard to k, he says that, if we wish to make the new geometry agree with the facts of experience, we must suppose k infinitely great in comparison with all known measurements.

For $k = \infty$, GAUSS's expression takes the usual form for the perimeter of a circle. (I)

(I) To show this we need only use the exponential series.

The same remark holds for the whole of GAUSS's system of geometry. It contains EUCLID'S system (as the limiting

case, when $k = \infty$.

1) Geometry of Quantum States... pdf

Pág. 08(21) - 1.2 High-dimensional geometry

In quantum mechanics the spaces we encounter are often of very high dimension; even if the dimension of Hilbert spaces is small, the dimension of the space of density matrices will be high. ...

We can improve ourselves by asking some simple questions about convex bodies in flat space.

A flat metric is assumed.

Obs: We choose to looks at balls, cubes and simplices for this purpose.

Our questions will concern the insphere and outsphere of these bodies (defined as the largest inscribed sphere and the smallest circumscribed sphere, respectively).

Looks: Pág. 12(25) - Figure 1.8.

Regular simplices in two, three and four dimensions. For Δ_2 we also show the insphere, the outsphere, and the angle in the feet.

For the simplex we obtain

$$\mathrm{vol}(\Delta_n) = \frac{1}{n!}\sqrt{\frac{n+1}{2^n}}. \qquad (1.25)$$

→

2) GeomMech1-2nd.pdf (007--GeomMech1-2nd.pdf)

Pág. 134(158) - 2.3. Hamilton.

Geometric optics may be approached either as a theory of systems of rays constructed by means of the elementary laws of refraction (Ibn Sahl, Snell, Descartes, Fermat, Newton), or as a theory based upon the consideration of systems of surfaces whose orthogonal trajectories are the rays (Huygens, Hamilton).

Pág. 135(159) - Hamilton optics, in which a characteristic function measures the time that light takes to travel from one point to another and it depends on the coordinates of both the initial and final points.

Pág. 136(160) - 2.3.1 Legendre Transform

One passes from Lagrangian to Hamiltonian dynamics through the Legendre transformation.

Voltando: (um pouco)

Pág. 112(136) - 2.2. Lagrange solution to the isoperimetric problem

Among all closed curves of a given fixed perimeter in the plane, which curve maximizes the area that it encloses?

The circle does this.

Pág. 113(137) - Example 2.2.1

Stereographic projection of $S^2 \to R^2$.

The unit sphere S^2 may be defined as a surface in $\mathbb{R}^3$ given by the set of points satisfying

$$S^2 = \{(x, y, z) : x^2 + y^2 + z^2 = 1\}.$$

<u>Important</u>:

Utilize the M.U.S (III) para recalcular a equação acima pois nós devemos observar que o resultado obtido será diferente da apresentação clássica. A nova geometria irá revelar a real realidade do comportamento dos objetos dentro do Universo. O ajuste das equações será necessário para que a realidade seja representada de forma eficaz e produzirá os efeitos necessários para o real entendimento do mundo e do Universo.

Estudando:

$$\tilde{\pi} = \tilde{\pi} \cdot F_L \cdot F_U \therefore \tilde{\pi} < \tilde{\pi}$$

Vejamos:

$$S^2 = [\{x, y, z) : x^2 + y^2 + z^2 = 1\} \cdot \tilde{\pi}]$$

ou

$$S^2 = [\{x, y, z) : x^2 + y^2 + z^2 = 1\} \cdot \tilde{\pi} \cdot F_L \cdot F_U]$$

Important:

O $\tilde{\pi}$ terá um valor fixado pois este número não representa a realidade a qual este número é usado para representá-lo.

$\tilde{\pi}$ sendo um valor fixo, multiplicado por 2 coeficientes que alteram este número e para menor valor, nós teremos a real clareza do Universo que queremos descrever de forma mais precisa.

$\tilde{\pi} < \tilde{\pi}$, o valor de $\tilde{\pi}$ representará a realidade do nosso mundo e o Universo.

The spherical polar angle θ and azimuthal angle ϕ are often used as coordinates on S^2. However, the angle ϕ cannot be defined uniquely at the north and south poles where $\theta = 0$ and $\theta = \pi$, respectively.

Important:

(Checar que com o uso do III, nós obteremos outros referenciais esféricos. Ficar atento aos efeitos nas equações envolvidas.

RIEMANN'S treatment used PTOLEMY'S (Ptolemy's) STEREOGRAPHIC PROJECTION to define two overlapping subsets that satisfied the defining properties of a smooth manifold.

Let $U_N = S^2 \setminus \{0,0,1\}$ and

$$U_S = S^2 \setminus \{0,0,-1\}$$

be the subsets obtained by deleting the north and south poles of S^2 respectively.

The stereographic projection

ϕ_N and ϕ_S from the north and south poles of the sphere onto the equatorial plane, $z=0$, are defined respectively by

$$\phi_N : U_N \to \xi_N + i\eta_N = \frac{x+iy}{1-z} = e^{i\phi}\cot(\theta/2),$$

and

$$\phi_S : U_S \to \xi_S + i\eta_S = \frac{x-iy}{1+z} = e^{-i\phi}\tan(\theta/2).$$

The union of these two subsets covers S^2. On the overlap of their projections, the coordinates

$(\xi_N, \eta_N) \in \mathbb{R}^2$ and

$(\xi_S, \eta_S) \in \mathbb{R}^2$ are related by

$$\boxed{(\xi_N + i\eta_N)(\xi_S + i\eta_S) = 1.}$$

<u>Important:</u>

Nós devemos prestar a atenção de que o valor igual 1 representa uma projeção sobre um plano. Isto deverá acontecer posteriormente com o espelhamento (mirror) ortogonal sobre um plano desta projeção. Assim, o valor deverá ser menor que 1 pois o valor III (M.U.S.) gera uma real adequação da projeção sobre um plano.

Figure 2.2:
In the stereographic projection of the RIEMANN sphere onto the complex plane from the north pole, complex numbers lying outside (resp. inside) the unit circle are projected from points in the upper (resp. lower) hemisphere.

Figure 2.3. In the stereographic projection of the Riemann sphere onto the complex plane from the south pole, complex numbers lying outside (resp. inside) the unit circle are projected from points in the lower (resp. upper) hemisphere.

Important: O plano x, y utilizado nas Figuras 2.2 e 2.3 deverá utilizar a curvatura F_L and F_U da equação III (M.U.S.) para simular as novas reconfigurações da projeção estereografica da esfera de Riemann.
(stereographic projection of the Riemann sphere onto the complex plane).

Newton Principles
1.1. The Task of Natural Philosophy

Newton does not understand by MOTION - MOTUS - every kind of quantitative and qualitative change, but only that which formerly called

MOTUS LOCALIS, that is,

locomotion or change of place.[2]

(2) → Newton, "De Gravitatione et Aequipondio Fluidorum", Def. 4, in Hall and Hall (1978), p. 31

Force - vis - is

"the causal principle of motion and rest."[3]

Newton distinguishes two kinds of force.

These two kinds of force are respectively the subject of Definitions IV and III of the "PRINCIPIA"

where the latter is referred to as "innate force (vis insita) of matter", and the former as "impressed force (vis impressa).

Innate force is said to be proportional to the "quantity" of matter - also called by Newton its "body" (corpus) or "mass" (massa) - and it is said to differ from the natural (inertia) of matter in our conception only.

Obs: "For a body perseveres in every new state by its force of inertia alone".

Stanley... - An Illustrative... pdf

Copy: 017 - - - Stanley... - An Illustrative.. pdf
Pág. 52(65) - Fig. 2.3
A 3D graph of a function of two variables.

obj: Usar TTI (M.U.S.) para recalcular a projeção ortogonal.

obs: A curvatura do z_1 acompanha a curvatura da forma geométrica humana (≡ Kitha).

$f: \mathbb{R}^2 \to \mathbb{R}$ of two variable is:

$$\lim_{P_1 \to P_0} \frac{f(x_0, y_0) - f(x_1, y_1)}{\sqrt{(x_1 - x_0)^2 + (y_1 - y_0)^2}} \qquad (2.1).$$

<u>Vejamos</u>:

The graphical foundation for the limit expression (2.1) is shown in Figure 2.3. The things to note are, firstly, the graph of f is suspended in 3D; secondly, the domain D_f lies in the xy-plane; thirdly, the points P_0 and P_1 in D_f give rise to values z_0 and z_1, respectively; and finally, the line in the domain joining P_0 and P_1 traces out the black curve in the graph of f.

In direct analogy with the 1D derivative we have

$$\Delta z = f(x_0, y_0) - f(x_1, y_1), \text{ and}$$

$$\Delta s = \sqrt{\Delta x^2 + \Delta y^2}.$$

Referring to Figure 2.3, for the limit process to make sense several related questions need to be addressed:

- does $f(x_0, y_0)$ exist, or equivalently, does (x_0, y_0) belong to D_f?

- is f continuous at (x_0, y_0)?
- does the limit $\lim_{P_1 \to P_0}$ exist if $P_1 \in D_f$?

Pág. 31(38) - Chapter 2

Schwarzschild Solution for Spherical Symmetry

See: Pág. 39(46) - Fig. 2.1

Gravity of spherical shell

Fig. 2.1

We have for a_y

$$a_y = \frac{2\pi r_s \cos\theta\, \mu (r_s \sin\theta - r_y)}{r^3}$$

The acceleration of the spacecraft due to the spherical shell or the acceleration of the spherical shell by the spacecraft is obtained by integrating a_y from θ equals -90 to 90 deg. The a_y component integrates to zero.

The Equation $\bar{a}_y = \int_{-\frac{\pi}{2}}^{+\frac{\pi}{2}}$ →

$$\bar{a}_y = \int_{-\frac{\pi}{2}}^{+\frac{\pi}{2}} a_y \, d\theta = \frac{2\pi M(r_y - r_y \sin\theta)}{r_y^2 (r_s^2 + r_y^2 - 2 r_s r_y \sin\theta)^{\frac{1}{2}}} \Bigg|_{-\frac{\pi}{2}}^{+\frac{\pi}{2}} = 0$$

This proves the shell theorem for $r < r_s$, which was first obtained by Newton. When r is greater than r_s, the acceleration is mass divided by r^2.

The shell theorem is also true for general relativity.

<u>Important</u>:

The proof is difficult because we cannot use the Euclidean model shown in Fig. 2.1.

<u>Obs</u>:

Acrescente a isto, o valor π e a sua representação geral na equação em questão.

Translations and Rotations

Pág. 100 - 14.11 Theorem

Each direct isometry is a rotation or a translation.

14.12 - Theorem →
the product of two translations is a translation.

Pág. 157 - Section 27
Applications of Similarities to elementary Geometry

27.2 Theorem - Three parallel lines cut off proportional segments from two transversals.

Pág. 158

Figure 27.2

27.2 Theorem – Three parallel lines cut off proportional segments from two transversals.

If the transversals are parallel, then the theorem follows immediately since opposite sides of the resulting parallelograms are congruent.

So suppose transversals ABC and $A'B'C'$ meet at P (Fig. 27.2).

Then $H(P, PB/PA)$ maps triangle PAA' to PBB' and $H(P, PC/PB)$ maps triangle PBB' to PCC'.

Now $AB/BC = A'B'/B'C'$ follows from similar triangles.

IMPORTANT:

Usar TH para recalcular as equações → MIRROR ORTHOGONAL.

Pág. 166 – Figure 28.7

28.8 – Compare the proof of theorem 28.7

with Corollary 20.8. (Pág. 126)

20.8 Corollary — If CABU, ABCV, and BCAW are parallelograms, then ABC is the medial triangle for triangle UVW.

Furthermore, the altitudes of triangle ABC concur by Theorem 20.1 since they are the perpendicular bisectors of the sides of triangle UVW (Fig 20.8)

(Fig 20.8)

obs: 20.1 Theorem (pág. 124) — The perpendicular bisectors of the sides of a triangle concur.

Voltando: 28.8

28.9 — The method of homothety is quite useful for constructions.

Pág. 218 – Section 37

Lines in the GAUSS PLANE

37.1 Theorem – Points A, B, C are collinear $\underbrace{\text{iff}}$

↳ definição matemática

Iff → if and only if (as a written abbreviation).

$$\begin{vmatrix} a & \bar{a} & 1 \\ b & \bar{b} & 1 \\ c & \bar{c} & 1 \end{vmatrix} = 0.$$

37.2 Theorem – An equation for the line passing through points A and B is

$$\begin{vmatrix} z & \bar{z} & 1 \\ a & \bar{a} & 1 \\ b & \bar{b} & 1 \end{vmatrix} = 0.$$

Clearly the equation is satisfied when $z = a$ and when $z = b$. The theorem then follows by Theorem 37.1.

As an alternative method of proof, expand the determinant to obtain the equation

$(\bar{a}-\bar{b})z-(a-b)\bar{z}+(a\bar{b}-\bar{a}b)=0.$

Writing $x+iy$ for z, so $\bar{z}=x-iy$, we find that the equation reduces to

$(\bar{a}-\bar{b}-a+b)x+i(\bar{a}-\bar{b}+a-b)$
$y(a\bar{b}-\bar{a}b)=0.$

<u>Obs</u>: Estudar!!!

Since each of these coefficients is pure imaginary, when we multiply through by i we obtain an equation of the form

$\alpha x+\beta y+\gamma=0$ for real α, β, γ.

This is an equation for a <u>STRAIGHT LINE</u>. (Pág. 219)

Pág. 227 – Section 39

<u>Isometries and Similarities in the GAUSS PLANE.</u>

Pág. 237 - Figure 41.4

41.5 Theorem → Inversion is a transformation of the inversive plane and is involutoric.

41.6 Theorem → Points inside the circle of inversion map to points outside the circle, and points outside map inside. Points on the circle are invariant (invariant) and are the only invariant points

If P lies inside the circle of inversion with center C and radius r, then $CP < r$.

Since $CP \cdot CP' = r^2$ then CP' cannot be less than or equal to r, for then

$$CP \cdot CP' < r^2.$$

Hence (por isso) $CP' > r$, so P' lies outside of circle.

41.7 - Definition → A transformation of the plane is called conformal iff it preserves angles between curves.

It is directly conformal if it preserves the sense of the angle as well, and inversely conformal if it reverses the sense.

41.8 Theorem - Isometries and similarities are conformal; direct similarities are directly conformal and ~~inv~~ opposite similarities are inversely conformal.

Pág. 238 - 41.10 Theorem

Inversion is inversely conformal.

PAQ and P'A'Q' are oppositely congruent.

Fig 41.10

Obs: Interessante!!!

ATENÇÃO:

41.11 Theorem

A line through the center of inversion is invariant.

41.12 Theorem

A line not through the center C of inversion maps into a circle through C.

Fig 41.12

Drop a perpendicular CP from the center C to given line m.
Let Q be any other point on line m (see Fig. 41.12).
Let P' and Q' be the inverses of P an Q.
By Theorem 41.9, triangles CPQ and CQ'P' are similar.
Hence $\measuredangle CQ'P' \cong CPQ = 90°$, so it follow that Q' lies on the circle of diameter CP'.

Since the ideal point maps to C, each point of line m maps to some point on that circle.

Furthermore, for each point Q' (other than C) on that circle, ray CQ' cuts line m in a point Q, and from the first paragraph of this argument, Q inverts to Q'. Hence the image of the line m is the entire circle on CP' as diameter.

Pág. 172 (187) Theorem 6.4.1 (Miquel's Theorem)

Given ΔABC and three merelaus points X, Y and Z, one on each side (possibly extended) of the triangle, then the circles formed using a vertex and its two adjacent merelaus points are concurrent at a point M.
The point of concurrency is called Miquel Point.

essa diferença decorre do erro do π, com o advento do π (M.U.S.) esperamos solucionar esta discrepância.

Obs: Estudar até pág. 176 (191).

Pág. 190 (205) - the Euler Line

Theorem 6.6.2 (Euler Line)

Given a nonequilateral triangle ABC, the circumcenter S, the centroid G, and the orthocenter H are collinear and form the Euler Line.

Obj: The circumcenter is the center of a triangle's circumcircle. It can be found as the intersection of the perpendicular bisectors.

The centroid is the centre point of the object. It is also defined as the point of intersection of all the three medians.

The median is a line that joins the midpoint of a side and the opposite vertex of the triangle.

The orthocenter is the intersection point of the altitudes drawn from the vertices of the triangle to the opposite sides.

For an acute triangle (is a triangle with three acute angles (less than 90°), it lies inside the triangle.

For an obtuse triangle (is a triangle with one obtuse angle (greater than 90°) and two acute angles), it lies outside of the triangle.

For a right-angled triangle, it lies on the vertex of the right angle.

In fact, G is a trisection of HS; that is, G is between H and S and $GH = 2GS$.

Note: If $\triangle ABC$ is equilateral, then $S = G = H$, and conversely, if $S = G = H$, then $\triangle ABC$ is equilateral.

→

obs: Veja a prova!!!

Pág. 193(208) - 6.7 the Steiner-Lehmus Theorem

Theorem 6.7.1. If the altitudes of a triangle are congruentes, then the triangle is isosceles.

Proof. In the figure on the following page, if $BD = EC$, then $\Delta BDC = \Delta CEB$ by the HSR congruence theorem.

Therefore, $\Delta ABD \equiv \Delta AEC$ by the ASA congruente theorem, so that $AB = AC$.
Therefore, $\angle B = \angle C$ and ΔABC is isosceles.

Theorem 6.7.2: If two medians of a triangle are congruent, then the triangle is isosceles.

Pág. 195 (210) - Theorem 6.7.3.

<u>the Fermat Point</u>

Let ABC be a triangle with $AB = 4$, $AC = 3$, and $\angle BAC = 30°$. Determine the minimum value of

$$PA + PB + PC$$

where P is any point inside the triangle ABC, and find the location of the point P that yields this minimum value.

Pág. 224 (239)

Solution: Consider the effect of $R_{A,60°}$ on ΔABC, as in the figure below. This maps ΔABC onto $\Delta A'B'C'$ and takes the point P to the point P'. Since $\angle PAP' = 60°$, triangle APP' must be equilateral. Hence

$$\begin{aligned} PB + PA + PC &= BP + PP' + P'C' \\ &\geq BP' + P'C' \\ &\geq BC' \end{aligned}$$

by the Triangle Inequality.

In mathematics, the triangle inequality states that for any triangle, the sum of the lengths of any two sides must be greater than or equal to the length of the remaing side. [1] [2]

cont. description Triangle Inequality:

This statement permits the inclusion of degenerate triangles, but some authors, especially those writing about elementary geometry, will exclude this possibility, thus leaving out the possibility of equality [3]. (A)

[3] Jacobs, Harold R. Geometry. p. 246 ISBN 0-7167-0456-0.

Obs: Degenerate triangle

A degenerate triangle has collinear vertices and zero area, and thus coincides with a segment covered twice (if the three vertices are not all equal; otherwise, the triangle degenerates to a single point). If the three vertice are pairwise (emparelhados) distinct, it has 0° angles and one 180° angle.

If two vertices are equal, it has one 0° angle and two undefined angles.

Theorem 37 - A quadrilateral is a parallelogram if two opposite sides are both equal and parallel.
Theorem 38 - Pág. 248 (268) →
A quadrilateral is a parallelogram if both pairs of opposite angles are equal

Theorem 39 ⇒ A quadrilateral is a parallelogram if its diagonals bisects each other.

Voltando ao estudo: (A)

Triangle Inequality

Now, $\angle BAC' = \angle BAC + \angle CAC' = 90°$, so $BC' = 5$ by Pythagoras' Theorem. Therefore, the value of $PA + PB + PC$ is at least 5, and the value will be exactly 5 if B, P, P', and C' are collinear.

Thus, to attain the minimum value, P and P' would have to lie on BC'.

If this happens, then

$\angle APB = 180° - \angle P'PA = 120°$ and

$\angle CPA = \angle C'P'A' = 120°$.

Now, this defines the point P uniquely, and since all three angles of triangle ABC are less than 120°, P is indeed inside ΔABC.

Pág. 225 (240) - Example 7.3.8.

A and B are the centers of two circles on the same side of line l.
Construct a line m, parallel to l, such that the circles cut off equal segments from m.

Solution. Let α and β denotes circles centered at A and B, respectively. Let P and Q be the feet of the perpendiculars from A and B upon l, respectively. The solution here is obtained by using the translation T_{PQ}.
Under this translation, the circle α is mapped to the circle α' centered at A', as in figure below.

Key figure:

$\Rightarrow$

Since the image of P is Q, we have $AA' = PQ$, and so $A'AP'Q$ is a rectangle.

Thus, A' must be on BQ.

Let E and F be the points at which the translated circle intersects B, and let m be the line EF, cutting α at C and D.

Then $E = C'$ and $F = D'$, so that

$$EF = C'D' = CD.$$

The triangle inequality therefore states that

$$(x+y, x+y)^{1/2} \leq \|x\| + \|y\|;$$

on squaring and expanding, this is seen to be equivalent to the

CAUCHY-SCHWARZ INEQUALITY.

7) 033--- Elementary Differential Geometry.pdf
→ 335 pp.

Pág. 22 (36) - Chapter 2 - Curve Theory.

Pág. 31 (45) - último parágrafo.

The first inequality above holds (aurra defeira) because of the
"TRIANGLE INEQUALITY"

$$\left| \|x\| - \|y\| \right| \leq \|x-y\|.$$

Pág. 66 (80)

The spherical side lengths are α_i, β_i and γ_i.

The triangle inequality gives that

$$\alpha_i \leq \beta_i + \gamma_i \qquad (2.18)$$

Using the spherical triangle with the vertices

$$\frac{a_{i+1} - a_i}{\|a_{i+1} - a_i\|}, \frac{a_{i+1} - a}{\|a_{i+1} - a\|} \text{ and}$$

$$\frac{a_{i+2} - a_{i+1}}{\|a_{i+2} - a_{i+1}\|}$$

We obtain analogously:

$$\alpha_{i+1} \leq \beta_{i+1} + \gamma_{i+1} \qquad (2.19)$$

We summarise:

$$K(P_2) - K(P_1) = \beta_i + \beta + \beta_{i+1} - (\alpha_1 + \alpha_{i+1})$$

$$= (\beta_i - \alpha_i) + \beta + (\beta_{i+1} - \alpha_{i+1})$$

$\geq -\gamma_i + \beta - \gamma_{i+1}$

$= 0,$

and hence $K(P_2) \geq K(P_1)$.

(b) Let us now assume that we are dealing with the equality case:

$$K(P_2) = K(P_1).$$

Then we must have equality in the triangle inequality (2.18),

$$\alpha_i = \beta_i + \gamma_i$$

Pág. 67 (81) →

Thus the vertices of the spherical triangle lie on a great circle, i.e.,

$a_i - a_{i-1}$, $a - a_i$ and $a_{i+1} - a_i$

lie in a two-dimensional subspace $V_1 \subset \mathbb{R}^3$. For suitable

$\lambda_1, \lambda_2 \in \mathbb{R}$ we have that

$a_i - a_{i-1} = \lambda_1 \cdot (a - a_i) + \lambda_2 (a_{i+1} - a_i)$

and thus

$$a_{i-1} = -\lambda_1 \cdot a - \lambda_2 \cdot a_{i+1} + (1+\lambda_1+\lambda_2) \cdot a_i \quad (2.20)$$

We now suppose that a_i, a and a_{i+1} are not collinear,

else (sensu) we would be dealing with case (1). Hence those three points span an affine plane

$$E \subset \mathbb{R}^3.$$

Because of (2.20) we also have $a_{i-1} \in E$.

It can be shown analogously that

$a_{i+2} \in E$. This proves (2).

Pág. 71 (85) →

To estimate the third term of (2.27) we observe that the triangle inequality for the spherical distances gives the inequality.

$$|\alpha_j - \beta_j| \leq \gamma_{j-1} + \gamma_j \quad (2.29)$$

Pág. 266 (284) — Appendix A

Hints for solution to (most) exercises

Pág. 271 (289) – 2.6

Let c be a curve connecting x and y which contains a point z that does not lie on the line segment $\overline{xy}$.
Then the triangle inequality shows that any polygon P having x, z and y as vertices must have length

$$L[P] \geq \|x-z\| + \|z-y\| > \|x-y\|.$$

Now choose a sequence of polygons approximating c which contain ~~x, y as~~ x, z and y as vertices.
Proposition 2.18 then says

$$L[c] \geq \|x-z\| + \|z-y\| > \|x-y\|.$$

→ Aprofundar com o resto da prova.

(b) → $\mathbb{R}^n$ be a parametrized curve connecting x and y.

Pág. 346 (372) - 7.2.2.
Shapiro effect via Fermat's principle
If a light signal is sent from Earth, located on the x-axis at $-x_E$, to Venus, say, which is located behind the Sun at x_V, as shown in Fig. 7.1, the light ray will be bent (dobrado) as it passes the gravitational field of the Sun.
Clocks will thus be slowed down, and the time it takes the ray to bounce (saltar) off the surface of Venus and return to Earth will be longer than if the sun were not present.
The simplest mechanical analog of the index of refraction is $n = \sqrt{(1-4\phi/c^2)}$, where ϕ is the potential energy per unit mass. We will justify this choice shortly. Since the gravitational field of the Sun makes the medium optically denser, ϕ can be identified as the gravitational potential, $-GM/r$,

where G is Newton's gravitational constant, M the mass of the Sun, and

$r = \sqrt{(R^2 + x^2)}$ is the distance from the center of the Sun to Venus, with R as the Sun's radius.

Fig. 7.1. The set-up for the ~~Spho~~ Shapiro effect.

Pág. 347 (373)

Now according to Fermat's principle, (7.2.3), the propagation time τ along a ray connecting the two endpoints $-x_E$ and x_V is given by

$$\tau = \int_{-x_E}^{x_V} \frac{\eta(r)}{c}\, dx = \int_{-x_E}^{x_V} \frac{\sqrt{(1 + 2\alpha/r)}}{c}\, dx,$$

where

$\alpha := 2GM/c^2$ is commonly referred to as <u>the Schwarzschild radius</u>.

Pág. 42(61) - (4)
Symmetries are the set $O(2)$ of rotation and reflection matrices

$$\begin{pmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{pmatrix} \text{ and } \begin{pmatrix} \cos\theta & \sin\theta \\ \sin\theta & -\cos\theta \end{pmatrix}$$

3.8 - Hyperbolic space
Consider $\mathbb{R}^3$ with the Lorentz quadratic form $q_L(V) = -t^2 + x^2 + y^2$ (compare B.2).

The cone $\{q_L(v) < 0\}$ break up into two subsets

$$\{t > +\sqrt{x^2+y^2}\} \cup \{t < -\sqrt{x^2+y^2}\}.$$

I fix the positive choice $t > 0$ throughout.

Pag. 43(62) – 3.9 <u>Hyperbolic distance</u>

$-v \cdot_L w = \cosh d(P, Q)$, so that

$$d(P, Q) = \operatorname{arccosh}(-v \cdot_L w); \quad (4)$$

in other words,

$$d(P, Q) = \operatorname{arccosh}(t_1 t_2 - x_1 x_2 - y_1 y_2).$$

<u>Lemma</u>: the Lorentz inner product satisfies

$$-v \cdot_L w = t_1 t_2 - x_1 x_2 - y_1 y_2 \geq 1,$$

with equality only if $P = Q$.

$\Rightarrow$ See also Exercise 3.11.)

Hence the distance $d(P, Q)$ is defined and positive unless (a not see qhe) $P = Q$.

Pag. 49(68) – 3.13 the hyperbolic plane in non-Euclidean

Theorem: Let $\mathcal{L}$ be a hyperbolic line and P a point not lying on $\mathcal{L}$.
Then there exists a unique perpendicular line PQ to $\mathcal{L}$ through P.
Moreover,

(1) if M is orthogonal to PQ in P, then the lines $\mathcal{L}$ and M diverge;

(2) there exists (exists) an angle $\theta < \frac{\pi}{2}$ with the property that if $\mathcal{L}'$ is a line through P, then $\mathcal{L}'$ meets $\mathcal{L}$ if and only if the angle of $\mathcal{L}'$ and PQ is less than θ
(See Figure 3.13.)

Pág. 269 (290) - 2 -
Some Facts from Non-Euclidean Geometry.

(Angle sum of T) $= \pi$.

Let's take our first look at how these new geometries differ from Euclid's.

A very familiar theorem of Euclidean geometry states that in any triangle T.

$$\text{Angle sum of } T = \pi.$$

As indicated in [1b], this result is actually equivalent to the

<u>parallel axiom.</u>

It follows that in non-Euclidean geometry the angle sum of a triangle differs from π. To measure this difference, we introduce the so-called angular excess E:

$$E(T) \equiv (\text{Angle sum of } T) - \pi.$$

Euclidean geometry is thus caracterized by the vanishing of $E(T)$.

Note that, unlike the original formulation of the parallel axiom, this statement can be checked against experiment:

construct a triangle, measures its angles, and see if they add up to π.

Gauss was the first person to ever conceive of the possibility that physical space might not be Euclidean, and he even (late) attempted the above experiment, using three mountain tops as the vertices of his triangle, and using light rays for its edges.

Within the accuracy permitted by his equipment, he found $E = 0$.

Quite correctly

GAUSS did not conclude that physical space is definitely Euclidean in structure, but rather (en vez de) that if it is not Euclidean then its deviation from Euclidean geometry is extremely small.

Let us return from physics to mathematics. Using pure logic to work out the consequences of (2) and (3), both Gauss and Johann Heinrich Lambert independently discovered that the two non-Euclidean geometries departed from Euclid's in opposite ways:

- In spherical geometry the angle sum is greater than π: $E > 0$.

• In hyperbolic geometry the angle sum is less than π: $E < 0$.

Furthermore, they discovered the striking (impressionante) fact $E(T)$ is completely determined by the size of the triangle.

More precisely, $E(T)$ is simply proportional to the area $A(T)$ of the triangle T:

$$E(T) = k A(T),$$

where k is a constant that is positive in spherical geometry and negative in hyperbolic geometry.

Chapter 8 - Part 6

Volume-23---20230826

Stefano Munich 2023042918 10.

- equation of the line is $x\cos\alpha + y\sin\alpha = p$ (1)
- coordinate axes are $x=0$ and $y=0$. (2)
- coordinate of O are $(0,0)$. (3)

Solving 1 and 2,

a) coordinate of A are $\left(\frac{p}{\cos\alpha}, 0\right)$

b) coordinate of B are $\left(0, \frac{p}{\sin\alpha}\right)$

↳ solving 1 and 3

Also;

$$AB = \sqrt{\left(\frac{p}{\cos\alpha} - 0\right)^2 + \left(0 - \frac{p}{\sin\alpha}\right)^2} =$$

$$= \sqrt{\frac{p^2}{\cos^2\alpha} + \frac{p^2}{\sin^2\alpha}} =$$

$$= \sqrt{\frac{p^2(\sin^2\alpha + \cos^2\alpha)}{\cos^2\alpha\,\sin^2\alpha}} =$$

$$\frac{p}{\cos\alpha\,\sin\alpha} \qquad OB = \frac{p}{\sin\alpha},\ OA = \frac{p}{\cos\alpha}$$

Find the equation of a straight line passing through the origin and having a given slope $\underline{\underline{m}}$.

$\therefore$ OB → straight line through O making an angle θ with the positive direction of x-axis.

Then its slope $m = \tan\theta$

Let $P(x, y)$ be any point on the line.

Draw $PM \perp$ x-axis so that

$OM = x$, $MP = y$.

From the right angled ΔOMP, we have

$$\tan\theta = \frac{MP}{OM} \quad \text{or} \quad \frac{y}{x} = m$$

$$\therefore \quad y = mx$$

Research: Including Pythagoras theorem

$a^2 + b^2 = c^2$ (retangle triangle)

<u>obs</u>: Inverse

equation:

$p = x \cdot \cos\alpha + y \cdot \sin\alpha$

M (slope) or

O + M

$\therefore$

$(0, 0) + (M, 0)$

or

$(x_1, y_1) + (x_2, y_2)$

$\therefore (x_1, y_1) + (M, y_2)$

distance $\overline{OM}$ =

$\sqrt{(x_1 - M)^2 + (y_1 - y_2)}$ obs: slope

$\therefore$

$O = A$ and $P = B$.

See: $O = A$.

$P = B$.

$M = O + M$ (slope) $\therefore$ equation

$p = x - \cos\alpha + y \cdot \sin\alpha$ obs: check $\begin{cases} y - \sin\alpha \\ \text{or} \\ y \sin\alpha \end{cases}$

Δ OMP is Pythagoras triangles.

Em resumo: Eu estou fazendo a unificação da equação da linha com a equação do triângulo retângulo pitagórico.

Há portanto, uma equação principal que poderá ser resolvida com os cálculos trigonométricos mais a equação da linha e uma sub equação interligando-se a equação de pitágoras. (triângulo inverso)

A primeira equação tem como origem (0,0) x-axis and y-axis

∴ x-axis → abscissa

y-axis → ordinate

A segunda equação em relação ao ponto M, origem do ângulo reto (90°).

Interessante:

Tive uma idéia:

a) criar equações trigonométricas em relação ao ponto M.

Obs: objetivo é fazer cálculos complementares em relação aos cálculos trigonométricos tradicionais.

a_1) primeiras equações em relação ao ponto O (0,0)

a_2) segundas equações em relação ao ponto M (x_2, y_2)

Importante!

Estas equações serão úteis para manter a integridade dos cálculos aplicáveis à curvatura tempo-espaço de Einstein.

↳ dinâmica.

Falando em Albert Einstein vejamos:

A unificação da teoria da relatividade e da teoria quântica depende do ajuste das equações à nova realidade considerando a gravidade como efeito das forças fundamentais da física.

a) eletromagnetismo;
b) força forte e
c) força fraca.

∴ A gravidade não existe!!!

Todo é verdade que no ambiente quântico a gravidade é desprezada por ser inexistente e o que há é a existência das forças fundamentais da física aplicáveis ao ambiente quântico.

Vejamos a minha equação:

M. U. S. I. C. H →

25. Geometria – Posição, Métrica e

Analítica — Curso Objetivo
Livro 25
Mauro Gruspan, Jorge Kritomian

Pág. 157 — nº 16

Determinar a equação da hipérbole cujos focos estão situados simétricamente em relação à origem e no eixo das ordenadas, sabendo que sua excentricidade vale $\frac{13}{12}$

→ valor ajustável à pesquisa

e que a distância entre seus vértices vale 48 unidades

→ ajustável à necessidade

off: Esta hipérbole pode representar a curvatura do espaço, acrescentado às equações trigonométricas tradicionais sobre a pitagórica (inversa).

→ início deste texto..

Calculando:

A partir do enunciado, temos:

Centro $C(0,0)$

- Eixo transverso: $2a = 48 \Leftrightarrow a = 24$
- Excentricidade:

$$e = \frac{f}{a} = \frac{13}{12} = \frac{f}{24} \Leftrightarrow f = 26$$

Como $f^2 = a^2 + b^2$ (Pitágoras), então

$$26^2 = 24^2 + b^2 \Leftrightarrow b^2 = 100 \Leftrightarrow b = 10$$

A equação da hipérbole, nas condições do problema, é:

$$\frac{y^2}{a^2} - \frac{x^2}{b^2} = 1, \text{ que resulta:}$$

(see)

$$\frac{y^2}{24} - \frac{x^2}{102} = 1 \Leftrightarrow \frac{y^2}{576} - \frac{x^2}{100} = 1$$

Esquema de terminar:

① Livro Co-ordinate Geometry

Pág. 64(67) - Example 5

Show that the distance of $P(x_1, y_1)$ from the line $ax + by + c = 0$ in the direction making an angle θ with x-axis is

$$-\frac{ax_1 + by_1 + c}{a\cos\theta + b\sin\theta}$$

Solution:

Let the line through $P(x_1, y_1)$ and inclined at an angle θ with x-axis meet the line $ax + by + c = 0$ in Q

Let $PQ = r$. We have to find r.

Co-ords. of Q are $(x_1 + r\cos\theta, y_1 + r\sin\theta)$

Q lies on $ax + by + c = 0$

$\therefore a(x_1 + r\cos\theta) + b(y_1 + r\sin\theta) + c = 0$

or

$(ax_1 + by_1 + c) + r(a\cos\theta + b\sin\theta) = 0$

or

$r(a\cos\theta + b\sin\theta) = -(ax_1 + by_1 + c)$

Hence $r = \dfrac{ax_1 + by_1 + c}{a\cos\theta + b\sin\theta}$, which

is the required distance.

Obs: usar sin com as anteriores anotações.

Voltando:

Pág. 61 - Straight line in distance form

To find the equation of a straight line passing through a given point (x_1, y_1) and making angle θ with the x-axis in the form

$$\frac{x - x_1}{\cos\theta} = \frac{y - y_1}{\sin\theta} = r$$

where r is the distance of any point (x, y) on the line from the point (x_1, y_1).

- Let $A(x_1, y_1)$ be the given point and AB, the line through A making an angle θ with the x-axis.
- Let $P(x, y)$ be any point on line such that

$AP = r$.

(Pág. 62) cont.

- Draw AL and PM perpendicular on the x-axis and AK perpendicular on MP.

Then $AK = NM = OM - ON = x - x_1$

$KP = MP - MK = MP - NA = y - y_1$

$\angle KAP = \angle XLP = \theta$

From the right angled triangle AKP, we have

$$\frac{x - x_1}{r} = \cos\theta \therefore \frac{x - x_1}{\cos\theta} = r. \quad (1)$$

$$\frac{y - y_1}{r} = \sin\theta \therefore \frac{y - y_1}{\sin\theta} = \theta \quad (2)$$

From 1 and 2, we have

$$\frac{x - x_1}{\cos\theta} = \frac{y - y_1}{\sin\theta} = r$$

which is the required equation

<u>Cor.</u> From $\frac{x - x_1}{\cos\theta} = \frac{y - y_1}{\sin\theta} = r$,

we have $\frac{x - x_1}{\cos\theta} = r$ and $\frac{y - y_1}{\sin\theta} = r$

$x = x_1 + r\cos\theta$;

$y = y_1 + r\sin\theta$ $\therefore$

thus the co-ordinates of the general point on the line are $(x_1 + r\cos\theta, y_1 + r\sin\theta)$.

alinhamento dos círculos (Sol e o círculo referência)

Pitágoras triangle.

I círculo base trasladado para a posição II, guardada as devidas proporções.

A equação da hipérbole representa a curvatura do espaço gerado pela massa do sol.

Alterando-se a excentricidade nós poderemos simular qualquer curvatura aplicável à qualquer massa solar do Universo. Criar um programa gerador da curvatura que será projetada sobre o plano para a obtenção do mirror local do M.U.S. (Mathematical Uniform Space).

Este programa servirá para todo o Universo.

<u>Important</u>: Unificar esta excentricidade com a excentricidade (ponto) da elipse $e = \frac{c}{a}$.
↳ planetas.

<u>Vejamos</u>:

Órbita elíptica:

$\Delta F_2 O B_2 =$ teorema de Pitágoras no triângulo retângulo

$a^2 = b^2 + c^2$

Vejamos:

a) focos da elipse: são os pontos fixos F_1 e F_2;

b) distância focal: é a distância $F_1F_2 = 2c$;

c) centro da elipse: é o ponto O, ponto médio do segmento $\overline{F_1F_2}$;

d) vértices da elipse: são os pontos A_1 e A_2;

e) eixo maior da elipse: é o segmento $\overline{A_1A_2}$, com $A_1A_2 = 2a$;

f) eixo menor da elipse: é o segmento $\overline{B_1B_2}$, com $B_1B_2 = 2b$ e

g) excentricidade: é a razão $e = \frac{c}{a}$, em que

$$0 < e < 1.$$

Importante: Esta órbita elíptica é paralela ao eixo x (abscissa) do gráfico da equação hiperbólica causadora da curvatura do espaço em decorrência da massa do Sol.

Excentricidades no espaço:

As trajetórias da Terra em torno do Sol e da Lua em torno da Terra são elipses com excentricidades respectivamente iguais a 0,016 e 0,054. Como essas excentricidades são muito próximas a zero, nós podemos dizer que essas elipses são praticamente circunferências.

$e = \frac{c}{a} = 0,016.$ $\qquad$ $e = \frac{c}{a} = 0,054.$

Equação reduzida da elipse:

Os focos são $F_1(-c, 0)$ e $F_2(c, 0)$.

Para um ponto $P(x, y)$ da elipse:

$d(P, F_1) + d(P, F_2) = 2a \Rightarrow$

$$\sqrt{(x+c)^2+(y-0)^2}+\sqrt{(x-c)^2+(y-0)^2}=2a$$

$$\sqrt{(x+c)^2+y^2}=2a-\sqrt{(x-c)^2+y^2}$$

<u>Obs.</u>: Aprofundar o estudo desta equação

<u>off</u>: Estudo complementar:

Secante e cossecante de um arco:

Traçando uma reta tangente à circunferência pelo ponto M, interceptamos o eixo das abscissas no ponto S e o eixo das ordenadas no ponto D.

Da figura, definimos $\sec x = OS$ e $\operatorname{cossec} x = OD$.

$$OS = \frac{1}{\cos x} = \sec x, \quad \cos x \neq 0 \text{ e}$$

$$OD = \frac{1}{\operatorname{sen} x} = \operatorname{cossec} x, \quad \operatorname{sen} x \neq 0.$$

<u>Quadro</u>:

	$y = \sec x$	$y = \operatorname{cossec} x$
Domínio	$x \neq \frac{\pi}{2} + k\pi,\ k \in \mathbb{Z}$	$x \neq k\pi,\ k \in \mathbb{Z}$
Imagem	$\sec x \leq 1$ ou $\sec x \geq 1$	$\operatorname{cossec} x \leq 1$ ou $\operatorname{cossec} x \geq 1$

Cotangente de um arco:

Definimos como cotangente do arco $\widehat{AM}$ a medida algébrica do segmento $\overline{BC}$, e indicamos

$$\text{cotg } x = BC$$

ou seja,
cotg x é a abscissa do ponto C.

Utilizando-se a semelhança de triângulos $\Delta\, OM'M \sim \Delta\, OBC$ podemos obter:

$$\boxed{BC = \frac{\cos x}{\operatorname{sen} x} = \text{cotg } x}$$ sendo

$\operatorname{sen} x \neq 0$, isto é, $x \neq k\pi$, $k \in \mathbb{Z}$.

Podemos escrever também:

$$\text{cotg } x = \frac{1}{\text{tg } x}, \quad x \neq k\frac{\pi}{2}$$

obs: Interessante (utilizar).

Voltando:

Relação trigonométrica fundamental

$OM = 1$

$OM' = \cos x$

$OM'' = MM' = \operatorname{sen} x$

No triângulo retângulo, $OM'M$, pelo teorema de PITÁGORAS, temos:

$$(MM')^2 + (OM')^2 = (OM)^2 \Rightarrow$$

$$(\operatorname{sen} x)^2 + (\cos x)^2 = 1^2$$ ou, ainda,

$$\operatorname{sen}^2 x + \cos^2 x = 1$$

Voltando: off:

$$D = \sqrt{a^2 + a^2 + a^2} = \sqrt{3a^2} \Rightarrow D = a\sqrt{3}$$

Usar o cálculo da distância entre os pontos diagonais de um cubo para calcular a distância entre a órbita elíptica de um planeta e o eixo x e y da equação hiperbólica.

□ ABCD representa o plano da equação hiperbólica

$\overline{AB}$ = abscissa x

$\overline{DA}$ = ordenada y

Distância entre dois pontos no plano cartesiano:

Pitágoras.

$$[d(A,B)]^2 = [d(A,C)]^2 + [d(B,C)]^2$$

Sendo $\overline{AC} \parallel Ox$ e $\overline{BC} \parallel Oy$, temos:

$d(A,C) = |x_2 - x_1|$ e

$d(B,C) = |y_2 - y_1|$

$$d(A,B)^2 = |x_2 - x_1|^2 + |y_2 - y_1|^2$$

Como:

$|x_2 - x_1|^2 = (x_2 - x_1)^2$ e

$|y_2 - y_1|^2 = (y_2 - y_1)^2$, concluímos que a distância entre os pontos A e B é dada

$$d(A,B)^2 = (x_2 - x_1)^2 + (y_2 - y_1)^2.$$

$$\boxed{d(A,B) = \sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2}}$$

<u>Voltando à equação reduzida da elipse</u>:

$$d(P,F_1) + d(P,F_2) = 2a \Rightarrow$$

Antes de voltar:

Consideremos uma reta r que intercepta o eixo x no ponto $A(p, 0)$ e o eixo y no ponto $B(0, q)$, com $p \neq 0$ e $q \neq 0$.

O coeficiente angular dessa reta é:

$$m = \frac{q - 0}{0 - q} = \frac{q}{-p} = -\frac{q}{p}$$

Então, a equação da reta r é:

$$y - y_1 = m(x - x_1) \Rightarrow$$

$$y - 0 = -\frac{q}{p}(x - p)$$

$$y = -\frac{q}{p}x + q$$

$$py = -qx + pq$$

$$qx + py = pq.$$

Dividindo ambos os membros por $pq \neq 0$, temos:

$$\frac{qx}{pq} + \frac{py}{pq} = \frac{pq}{pq} \Rightarrow \frac{x}{p} + \frac{y}{q} = 1$$

Sec. Posições relativas de duas retas

l_1 e l_2 são perpendiculares ($l_1 \perp l_2$).

Consideremos duas retas l_1 e l_2 concorrentes num ponto P, de tal forma que nenhuma delas seja vertical e $l_1 \perp l_2$.

Do triângulo APB, vem

$$\alpha_1 = \alpha_2 + 90° = tg\,\alpha_1 (\alpha_2 + 90°)$$

$$tg\,\alpha_1 = \frac{sen(\alpha_2 + 90°)}{cos(\alpha_2 + 90°)}$$

$$tg\,\alpha_1 = \frac{sen\,\alpha_2 \cdot cos\,90° + sen\,90° \cdot cos\,\alpha_2}{cos\,\alpha_2 \cdot cos\,90° - sen\,\alpha_2 \cdot sen\,90°}$$

$$tg\,\alpha_1 = \frac{cos\,\alpha_2}{sen\,\alpha_2} \Rightarrow tg\,\alpha_1 = \frac{1}{tg\,\alpha_2}$$

Como $tg\,\alpha_1 = m_1$ e $tg\,\alpha_2 = m_2$, temos

$$tg\,\alpha_1 = -\frac{1}{tg\,\alpha_2} \iff m_1 = -\frac{1}{m_2}.$$

Voltando:

Equação reduzida da elipse

$$d(P, F_1) + d(P, F_2) = 2a \Rightarrow$$

$$\sqrt{(x+c)^2 + (y-0)^2} + \sqrt{(x-c)^2 + (y-0)^2} = 2a$$

$$\sqrt{(x+c)^2 + y^2} = 2a - \sqrt{(x-c)^2 + y^2}$$

Tendo como: $F_1(-c, 0)$ e $F_2(c, 0)$

x x

$$x - (-c) = (x+c)^2$$

Elevando os dois membros ao quadrado:

$$(x+c)^2 + y^2 = 4a^2 - 4a\sqrt{(x-c)^2 + y^2} + (x-c)^2 + y^2$$

Resolvendo a equação: teremos

$$\cancel{x^2} + 2cx + \cancel{c^2} + \cancel{y^2} =$$

$$4a^2 - 4a\sqrt{(x-c)^2+y^2} + \cancel{x^2} - 2cx + \cancel{c^2} + \cancel{y^2}$$

Eliminando os dois lados, teremos:

$$4a\sqrt{(x-c)^2+y^2} = 4a^2 - 4cx$$

Dividindo os 2 membros por 4, teremos:

$$a\sqrt{(x-c)^2+y^2} = a^2 - cx$$

Elevando os dois membros ao quadrado:

$$a^2[(x-c)^2+y^2] = (a^2-cx)^2$$

$$a^2(x^2-2cx+c^2+y^2) = a^4 - 2a^2cx + c^2x^2$$

$$a^2x^2 - \cancel{2a^2cx} + a^2c^2 + a^2y^2 =$$

$$a^4 - \cancel{2a^2cx} + c^2x^2$$

$$x^2(a^2+c^2) + a^2y^2 = a^2(a^2-c^2)$$

Como ~~a^2+b~~ $a^2 = b^2 + c^2$, podemos escrever

$$a^2 - c^2 = b^2$$

$$b^2x^2 + a^2y^2 = a^2b^2$$

Dividindo os dois membros por a^2b^2 ($b>0$, $a>0$):

$$\frac{b^2x^2}{a^2b^2}+\frac{a^2y^2}{a^2b^2}=\boxed{\frac{x^2}{a^2}+\frac{y^2}{b^2}=1}$$

Como o eixo maior da elipse está contido no eixo x e a e b são positivos, então $a>b$. Assim, o denominador de x^2 é maior que o denominador de y^2.

Resumo

$\frac{x^2}{a^2}+\frac{y^2}{b^2}=1$ é a equação da elipse quando o eixo maior está contido no eixo x.

$\frac{x^2}{b^2}+\frac{y^2}{a^2}=1$ é a equação da elipse quando o eixo maior está contido no eixo y.

IMPORTANT: ✡

Aprofundar pesquisa para desenvolver os cálculos como uma função hyperbólica ou como uma função parabólica.

→ acho melhor, pois permite o uso de retas paralelas à diretriz e

o uso do arco da circunferência como um elemento verificador redundante dos cálculos. + eixo de simetria

Vejamos então:

(Obs): O foco pode ser o centro da estrela, i.e., o Sol.

$P_1F = P_1D_1$

Portanto:

a) foco da parábola é o ponto F;
b) reta diretriz é a reta d;
c) eixo de simetria é a reta que passa pelo foco F e é perpendicular à diretriz e
d) vértice da parábola é o ponto V, ponto médio do segmento FD, isto é, $VF = VD$.

$d(P,F) = d(P,d) \Rightarrow$

$\sqrt{(x-0)^2+(y-p)^2} = \sqrt{(x-x)^2+(y+p)^2}$

$x^2+(y-p)^2 = y^2+2py+\cancel{p^2}$

$x^2+\cancel{y^2}-\cancel{2py}+\cancel{p^2} = \cancel{y^2}+\cancel{2py}+\cancel{p^2}$

somem-se

$x^2 = 2py+2py$

$x^2 = 4py$ ou $y = \frac{x^2}{4p}$,

que são equações reduzidas da parábola de foco $(0,p)$ e diretriz $y=-p$.

<u>Important</u>

Construção de uma parábola.

r_1, r_2 e r_3 // d (à diretriz)

<u>obs</u>: Com centro em F e raio A_1D, traça-se o <u>arco de circunferência</u> que intercepta r_1 nos pontos P_1 e P_1'.

etc...

Logaritmos:

$\log_{10} 1385 = 3,141449...$

<u>Important</u>:

$\log_a b$ para existir, devemos ter

- logaritmando positivo: $b > 0$
- base positiva e diferente de 1:

$a > 0$ e $a \neq 1$.

Usar o logaritmo para representar a equação da curvatura do espaço.

Ex: Para quais valores reais de x existe

$$\log_{x+1}(x^2+3x-18)?$$

Devemos ter: $\begin{cases} x^2+3x-18>0 & (I) \\ x+1>0 \text{ e } x+1\neq 1 & (II) \end{cases}$

Resolvendo as condições (I) e (II), temos:

$x^2+3x-18>0$ (I)

$$x = \frac{-3\pm 9}{2} \begin{cases} x' = 3 \\ x'' = -6 \end{cases}$$

$x+1>0$ e $x+1\neq 1$ (II)

$x>-1$ $\qquad$ $x\neq 0$

Fazendo a intersecção dos conjuntos soluções de (I) e (II), obtemos:

$\log_{x+1}(x^2+3x-18)$ existe para $x>3$.

<u>Propriedades dos logaritmos:</u>

1) $\log_b(a.c) = \log_b a + \log_b c$, com $a>0$, $c>0$ e $1 \neq b > 0$

2) $\log_b \frac{a}{c} = \log_b a - \log_b c$, com $a>0$, $c>0$ e $1 \neq b > 0$.

3) $\log_b a^n = n \log_b a$, com $a>0$, $1 \neq b > 0$ e $n \in \mathbb{R}$.

(prestar atenção)

Usando as propriedades dos logaritmos

na resolução de sistemas:

$$\begin{cases} x + y = 100 \\ \log x + \log y = 3 \end{cases}$$

$x > 0$ e $y > 0$

- aplicando-se a propriedade do logaritmo de um produto na 2ª equação, obtemos:

$$\log x + \log y = 3 \Rightarrow$$
$$\log(x \cdot y) = 3$$

- Usando a definição de logaritmo, vem:

$$\log(x \cdot y) = 3 \Rightarrow xy = 10^3$$
$$xy = 1000$$

Temos então o sistema equivalente

$$x + y = 110 \quad (I)$$
$$xy = 1000 \quad (II)$$

De (I), vem: $x = 110 - y$ (III)

Substituindo (III) em (II), resulta:

$(110 - y)\, y = 1000$

$y^2 - 110y + 1000 = 0 \quad \begin{cases} y' = 100 \\ y'' = 10 \end{cases}$

Substituindo os valores de y em (III), obtemos:

$y = 100 \Rightarrow x = 110 - 100 \Rightarrow x = 10$

ou

$y = 10 \Rightarrow x = 110 - 10 \Rightarrow x = 100.$

Como esses valores satisfazem as condições de existência, temos:

$x = 10$ e $y = 100$ ou

$x = 100$ e $y = 10$

$S = \{(10, 100), (100, 10)\}$

<u>Cologaritmo</u>:

$\log_a \frac{1}{b} = -\log_a b = \text{colog}_a\, b,$

com $b > 0$ e $1 \neq a > 0$

202304301630 Achar o centro de um círculo:

Meu método:

1) Pegue o círculo (qualquer) e com o compasso abra com o mesmo tamanho do diâmetro do círculo.

2) Faça um círculo a partir do ponto A com o diâmetro do círculo que se quer achar o centro.

(X) (3) Faça outro círculo do outro lado no ponto B. (completo). no ponto o primeiro círculo encontrar o círculo oposto.

4) Estes dois círculos se encontram nos pontos C e D e em seguida, trace uma reta ligando estes pontos. (tracejado).

5) Ao fazer isto, você encontra os pontos E e F sobre o círculo que se quer encontrar o centro do círculo.

6) Nos pontos E e F faça o mesmo procedimento com o compasso com o diâmetro do círculo que se quer encontrar o centro. Ao fazer isto você irá ver os pontos G e H sobre estes pontos trace uma linha tracejada.

7) Ao fazer isto as retas $\overline{CD}$ e $\overline{GH}$ se interceptarão no centro do círculo (perpendicularmente) que se quer achar o centro. (Ponto O).

Important: ⊗ da questão

⊗ O ponto A (inicial) é escolhido aleatoriamente, ou seja, um ponto qualquer sobre o círculo que se quer encontrar o círculo.

Ao fazer um círculo com o diâmetro do círculo original sobre o ponto A, vai encontrará o ponto B quando o mesmo tocar o círculo original que se quer encontrar o círculo.

Veremos outro método:

Livro: Álgebra linear y Geometria
Gallo
Pág. 337 (351)

Usando mediatrices.

O = circuncentro (centro do círculo)

Demonstração:

1) Pegue o círculo que se quer achar o centro.

2) Desenhe um triângulo inscrito no círculo - ΔABC

3) Ache a mediatriz das faces do triângulo inscrito.

3a) Comece pelo ponto A;

3b) Faça o círculo ponto B;

3c) Depois faça no ponto C.

Desta forma, você achou todas as mediatrizes das faces de um triângulo inscrito.

Marcando os ponto:

3a) No ponto A faça um círculo com diâmetro maior que o raio e menor que o diâmetro do círculo no qual está inserido o ~~círculo~~ triângulo inscrito.

3b) No ponto B faça outro círculo utilizando-se da mesma medida utilizada no ponto A. Desta forma, você encontrará os pontos D e E, trace uma reta tracejada ligando estes pontos, neste ponto, esta reta irá interceptar a reta AB (face de um triângulo), fazendo um ângulo 90°.

3c) Com o compasso, utilize a mesma medida utilizada para desenhar os outros círculos sobre o ponto C. Neste momento, você acaba de criar os outros pontos para você achar a mediatriz das duas faces do triângulo inscrito restantes, ou seja, F G (pontos) e os pontos H e I.

Portanto, teremos as retas:

a) $\overline{DE}$ (intersecção dos círculos criados a partir dos pontos A e B).

b) $\overline{FG}$ e $\overline{HI}$ criadas pelo círculo criado sobre o ponto C.

obs: El circuncentro de un triángulo rectángulo se halla en el punto medio de su hipotenusa.

Importent: Este procedimento para achar o centro de um círculo vale para o caso de uma circunferência inscrita em um triângulo qualquer (não precisa ser um triângulo retângulo)

obs. Las bisectrices de los ángulos interiores de un triángulo se cortam en un solo punto que coincide con el centro de la circunferencia inscrita en él.

Atenção: Com o triângulo retângulo você poderá utilizar a mediatriz.

20230523 0633

Lavenda wrote A New Perspective on Thermodynamics, published in 2009, by returning to Carnot's original conception that work can only be done when there is a difference in temperature, and the necessity of closing the cycle before that work can be assessed.

More recently Lavenda has directed his interests to relativity by providing it with a new foundation based on non-Euclidean geometries.

(Book: A New Perspective on Relativity — Bernard H. Lavenda
An Odyssey in Non-Euclidean Geometries) — 2012 — 695 pp.

Rather than measuring distances in terms of the usual Euclidean metric, distances are defined in terms of what is know as a cross-ratio, a perspective invariant of four points, which, for the space of velocities, just happens to be compounding of longitudinal Doppler shifts.

Doppler shifts are fundamental to relativity: oblique Doppler shifts describe aberration, while second

orders ones <u>lengthwise length contraction</u>, but rather than being in the direction of the motion are perpendicular to it.

The <u>uniform rotating disc</u>, which is considered by some to be missing link in <u>Einstein's formulation of general relativity</u>, is exactly described by the <u>hyperbolic metric in polar coordinates</u>, named after the nineteenth century italian geometer Eugenio Beltrami, which predicts the circumference of the disc to be greater when in motion than when it is at rest. Thus a uniform rotating disc belongs to hyperbolic, and not Euclidean, space and so, too, does relativity.

<u>Critica:</u>

Questa analisi è quasi del tutto vera ma non perpendicolarmente, ma secondo un nuovo approccio matematico. (20230522)

email: bhaverda@gmail.com

This analysis is almost entirely true, but not perpendicularly, but according to a new mathematical approach

Lavenda: (text) email 20230523061 9

The Doppler is well know that it is linked to special relativity. But considering the longitudinal Doppler, the displacement is proportional to the ratio c + v and c − v, where v is the speed of the mobile. This seems to contradict the fact that nothing can travel faster than the speed of light (Ritz's ballistic theory of light). This was mentioned in the book by Louis Essen (1972) who criticized special relativity saying it is just a new unit of measurement instead of a (new) new theory.

(Distance, time, and velocity. Which of the two do you want to keep constant?)

Also, the logarithm of the longitudinal Doppler is a distance in the hyperbolic plane (Poincaré), where c is a unit of measure and not an absolute speed. So it depends on the geometry you're considering.

Research and analysis:

Longitudinal Doppler Effect

The longitudinal Doppler effect considers the simple case of a source moving

directly towards you or away from you along a straight line.
The transverse Doppler effect considers what is observed when the observer is displaced in a direction perpendicular to the direction of the motion.

Answer:

(1) Tanto the longitudinal Doppler Effect quanto the transverse Doppler Effect usam como parâmetro a linha reta (straight line)
→ referencial.
Para mim, a questão teta está como nós entendemos o conceito de uma linha reta em um universo curvo, sua projeção ortogonal e os seus decorrentes consequências sobre o mundo e o universo no qual nós estamos inseridos.
O valor do número Pi, ou melhor, o meu novo valor do número PI - M.V.S. traduz este conflito intrínseco ao qual os nossos estudos estão submetidos de forma quase angustiável, mas que para mim, está errado e incompleto, sujeito, portanto, ao questionamento inevitável.

50 pp.

Pág. ~~3~~ 4 (find: Essen)

If time dilatation and space contraction due to motion are actual processes then there is no symmetry between observers in different inertial frames. The first postulate of relativity is therefore violated [Essen 71].

obs: Einstein used gedanken experiments which is an oxymoron.

(figure language)

Einstein [16] has to say about a pair of local observers on a rotating disc

→ time slowly.

Pág. 5 → velocidade da luz.

If the velocity of light is independent of the velocity of its source, how then can the outward journey of a light signal to an observer moving at velocity v be $c+v$, or its return it travels with a velocity $c-v$?

Although this violates the second postulate, such assertions appears in the expression for the elapsed time of sending out a light signal from one point to another and back again in the

Michelson-Morley experiment

whose null result they hope to explain.

They also appear alongside Einstein's substitute velocity composition law in his famous 1905 paper "On the Electrodynamics of Moving Bodies".

Important:

Also in that paper is his "definition" of the velocity of light as the ratio of "light path" to the "time interval".

But we are not allowed to measure the path of the light ray and determine the time it took, for c has been elevated to a universal constant.

"How can two units of measurement be made constant by definition?"
Essen queries.

observação referencial atinente aos movimentos dos objetos em estudo.

Answer to Lavenda (20230523)

(X) in italian..
(traduzi para o inglês)

Dear Lavenda

In the first place, we must note that both the longitudinal and the transversal Doppler effect use a reference observation parameter relating to the movements of the objects under study and, consequently, we cannot consider the velocity (log Doppler) comet, as there is a mathematical divergence in the calculation process.

Gauss and Weber built electrodynamics on its basis, considering magnetic and induction forces as a consequence of changes in electric forces, but Weber was a proponent of the theory of actions at a distance, where the value of c tends to infinity, ceasing of being a constant and becoming a limit of measurement.

Gauss adhering to the exact opposite principle, considering that the impact is transmitted not instantly, but with a delay (delay), through an intermediate

agent (ether - standard microparticles).
Ritz reducing magnetic effects to efetric (electric)
conto: to electrical one, initiated by Ampere considering magnetism as a fiction.
Ritz's theory, unlike the Biot-Savart law does not contradict the law of conservation of momentum, following Maxwell's theory.
Ritz explained not only all magnetic effects, but also the phenomenon of electromagnetic induction discovered by Faraday.
The electrodynamic effects are a direct consequence of the Doppler effects and Ritz (effects).
The electrodynamic effect are a direct consequence of the spatio-temporal relativistic (space-time) discovered by the Ritz and delay electrical signals.
Doppler and Ritz effects generate the same induction.
Another important aspect has to be considered, most possibilities have emerged in this quantum spacetime phenomenology, influencing the standard theoretics of SR in a different way:
either the Lorentz invariance is broken, which implies the

existence of a privileged ~~frame~~ frame of reference, or the SR symmetries are warped, as in the so-called "Special Double Relativity" (DSR) scenario, so that a relativity principle is still present.

I say this, because Essen claims that the first postulate of relativity has been violated, because there is no symmetry and observers in different inertial frames.

(entre) (in between)

Therefore, we need to do a deeper analysis of these paradigms.

To see light can travel beyond the speed established by Einstein's theory, depending on the reference used in the study light has speed, but accessing it can violate this postulate. The speed of light is not only higher due to thermodynamics and entropy.

The matter is in the "light path" and "time interval", analyzed by Essen, and I go further, which is not the case here.

Pág. 01 (12) — Convexity.

Em relação $\underline{\underline{K}}$; devemos adaptar aos cálculos obtidos pelo $\widetilde{III}$ (M.U.S.) — Mathematical Uniform Space.

$K \geqslant 0$, $K = 0$ e $K \leq 0$, apresentamos deformados em relação à curvatura do espaço-tempo.

$\widetilde{III}$ (M.U.S.) representa a real qualidade do comportamento do espaço-tempo do Universo.

Portanto, obtemos

$$\widetilde{K\,III} \geqslant 0, \underbrace{\widetilde{K\,III} = 0}, \text{ e } \widetilde{K\,III} \leq 0$$

esta parte do cálculo é uma representação teórica ajustada aos parâmetros matemáticos, mas na realidade uma representação plana de um Universo curvilíneo apresenta as suas peculiaridades bem interessantes.

O interessante que esta representação vê ajudar a comprovar os cálculos do $\widetilde{III}$ (M.U.S.), pois ao calcular uma linha reta (distância entre dois pontos) com a curvatura do Universo devidamente projetado sobre um plano, nós teremos uma real visão da realidade do Universo.

Chapitre I - Ligne Droite
I. Points en ligne droite.

1. Démontrer que dans un quadrilatère complet les milieux des diagonales sont en ligne droite.
Disassemble that in a complete quadrilateral the diagonal media are in a straight line.
Demontre que em um quadrilátero completo o meio diagonal está em linha reta.
(Interessante)

On appelle quadrilatère complet la figure formée par quatre droites dont trois ne passent pas par un même point et dont deux ne sont pas parallèles

The figure formed by four lines is called complete quadrilateral, three of which do not pass through the same point and two of which are not parallel.

A figura formada por quatro linhas é chamada quadrilátero completo, três das quais não passam pelo mesmo ponto e duas das quais não são paralelas.

English:

1. Prove that in a complete quadrilateral the midpoints of the diagonals are in a straight line.

We call complete quadrilateral the figure formed by four straight lines, three of which do not pass through the same point and two of which are not parallel.

These lines are called the sides of the quadrilateral, and the meeting points of these lines taken two by two are the vertices of the quadrilateral; there are therefore six vertices.

If we join the meeting points of <u>any</u> two sides at the point of the

other two, we obtain a line the diagonal of the quadrilateral. We then see that there are three diagonals and we propose to demonstrate that the midpoints of these diagonals are in a straight line.

Fig. 1.

Let us take as coordinate axes two sides of the quadrilateral (x and y).
let the other two be AB and A'B', which intersect at point C.
The three diagonals are then AB', A'B and OC;
their midpoints are the points M. N. P.
We will calculate the coordinates of these points.
Let a, a' be the abscissa of points A, A'; b and b' the ordinates of points B, B'.

The coordinates of point M are

$$x' = \frac{a}{2}, \quad y' = \frac{b'}{2},$$

and those of points N,

$$x'' = \frac{a'}{2}, \quad y'' = \frac{b}{2}.$$

To have the coordinates of point P, midpoint of OC, it is enough to know those of point C.

Now this point is at the intersection of the lines AB and A'B' which respectively have the equations

$$\frac{x}{a} + \frac{y}{b} - 1 = 0,$$

$$\frac{x}{a'} + \frac{y}{b'} - 1 = 0;$$

consequently, to have the coordinates of point C it is necessary to solve these two equations.

We thus obtain

$$x = \frac{a a'(b'-b)}{ab' - ba'}, \quad y = \frac{-bb'(a'-a)}{ab' - ba'};$$

the coordinates of point P, midpoint of OC, are then:

$$x''' = \frac{aa'(b'-b)}{2(ab'-ba')},$$

$$y''' = -\frac{bb'(a'-a)}{2(ab'-ba')}.$$

To establish that the points M, N, P are in a straight line it is necessary to prove the equality

$$\frac{y'''-y'}{x'''-x'} = \frac{y''-y'}{x''-x'}.$$

Or, on a

$$\frac{y'''-y'}{x'''-x'} = \frac{-\frac{bb'(a'-a)}{2(ab'-ba')} - \frac{b'}{2}}{\frac{aa'(b'-b)}{2(ab'-ba')} - \frac{a}{2}} =$$

$$\frac{-bb'(a'-a) - b'(ab'-ba')}{aa'(b'-b) - a(ab'-ba')},$$

$$\frac{y'''-y'}{x'''-x'} = \frac{b-b'}{a'-a}.$$

On the other hand, we easily see that

$$\frac{y'' - y'}{x'' - x'} \text{ is equality}$$

~~(is equality (is therefore verified and the proposition is established.)~~

$$\frac{b - b'}{a' - a}.$$

The equality is therefore verified, and the proposition is established.

<u>Análise</u>:

Partindo-se do pressuposto que há uma linha reta e somando-se ao uso do teorema de Pappus, nós poderemos ter várias aplicações.

a) usando-se duas linhas partindo do ponto O, nós poderemos ter várias utilidades geométricas. Vejamos:

a1) <u>no plano</u> (qualquer) traçamos duas linhas sem saber qual a sua relação entre si, ou seja, nós sabemos qual é a equação que define cada linha.

Mesmo assim, nós podemos achar esta linha reta.

a_2) plano curvo ou esfera
usando-se este princípio:
b1) duas retas
b2) partindo-se do mesmo ponto;
Nós podemos continuar a obter uma linha reta que está descrita sobre um plano curvo ou esfera.

b) utilizando-se duas retas e um mesmo ponto, nós podemos utilizar o Teorema de Pappus (3 pontos) para estabelecer uma reta também.
Obs.: Nós não podemos esquecer que
AB' e A'B não são linhas paralelas.
↳ importante uso para obtenção de uma linha reta com relação a um ponto fora destas duas retas e que no caso é o ponto O.

Vejamos:

P M and N
→ 3 points
(Pappus)

Obs: Aplicar também ao plano curvo e a esfera.

Importantíssimo:

Aplicar também à minha pesquisa

M.U.S.

Neste aspecto:

nós criaremos um novo tipo de linha reta, ou seja, não é uma linha reta no plano, nem no plano curvo e nem na esfera.

Nós obteremos uma linha reta no plano M.U.S. projetado ortogonalmente em um plano matemático (teórico), mas não real, sendo o real deformado e outros valores!

Obs.: Difference between Orthic Triangle and Pedal Triangle.

Source: https://math.stackexchange.com/questions/3146011/difference-between-orthic-triangle-and-pedal-triangle

A pedal triangle is defined by an arbitrary point. (The vertices of the pedal triangle are where the feet of perpendiculars from that point meet the side-lines of the original triangle).

The orthic triangle is specifically the pedal triangle determined by the original triangle's orthocenter

Return: Pedal Triangle

The pedal triangle has vertices that are the feet of the perpendiculars from the pedal point to each of the sides of the original triangle.

Consider degenerate:

A pedal triangle that is completely outside the original triangle.

Important: When the pedal point is on a vertex of the

original triangle, the pedal triangle degenerates into the altitude of the original triangle.

Obs:

a) When the triangle is acute the pedal triangle (altitude) is inside the original triangle.

b) When the triangle is right, the pedal triangle (altitude) lies along one of the side of the original triangle.

c) When the triangle is obtuse the pedal triangle (altitude) lies outside the original triangle.

Def: Centroid of a triangle is the point where the three medians of a triangle meet.

Orthocenter of a triangle is the intersection point of the altitudes drawn from the vertices of the triangle to the opposite sides.

The Frégier Mapping
A Quadratic Transformation

Place of action is the projective enclosed Euclidean plane P^2.

We declare the (planar) Frégier mapping

$\gamma : P^2 \to P^2$ to fixed points

O and F follows:

Connect a given point P_1 with O, draw the line g_2 orthogonal to $OP_1 =: g_1$ through O and intersect g_2 with line $FP_1 =: f$.

The intersection points $P_2 =: P_1^\gamma$ acts as Frégier image of P_1.

see Fig. 5.
Let P_1 run through a line l, then $f \to g_1$ is a perspectivity.
As $g_1 \to g_2$ is an involutoric projectivity, the mapping
$f \to g_2$ is at least a projectivity.
It is well-known that projective pencil $\{g_2\}$ and $\{f\}$ generate a conic l^Y
this in mind we can already recognise Y as a
quadratic transformation.
As P_2 maps to P_1 again, Y obviously is involutoric.
We give the analytic description of Y on a cartesian coordinate frame and use homogeneous coordinates:

$O = (1, 0, 0)\mathbb{R}$, $F = (1, 0, 1)\mathbb{R}$,
$P_1 = (1, x_1, y_1)\mathbb{R}$, $P_2 = (1, x_2, y_2)\mathbb{R}$

(I)

= x

Scalene barycentre (ângulo + middle point) (α, β, γ) I

Scalene Triangle A, B, C Δ.

Segmento $\overline{xz}$ é 1/2 dos segmentos $\overline{BC}$, $\overline{BD}$ e $\overline{CD}$.

Obs: Δ BCD isósceles triângulo.

Δ ACE - isósceles

A mediatriz de um lado é igual a bissetriz do ângulo oposto à reta que se fez e mediatriz (perpendicular barycenter)

A linha I é a mediatriz do segmento $\overline{CE}$ e bissetriz do ângulo A do triângulo Δ ACE.

Segmento $\overline{xw}$ = $\overline{xz}$ = $\overline{kx}$

Em vez do quadrado usaremos triângulos.

(II)

Estudo: (quadrilátero). (II)

a) Segmento $\overline{AB}$ é cortado perpendicularmente pela linha 1. (perpendicular bisector) - mediatriz.

b) Segmento $\overline{CD}$ é cortado perpendicularmente pela linha 2. (perpendicular bisector)

c) Segmento $\overline{DB}$ → linha 3.

d) Segmento $\overline{AC}$ → linha 4.

Análise: (das linhas)

a) Linha 1 → não faz ângulo de 90° com nenhuma reta (2, 3, 4).

b) Linha 2 → faz ângulo de 90° com a linha 3.

c) Linha 4 → faz um ângulo maior que 90° com a linha 1.

Interessante:

A Linha 1 e a Linha 2 se interceptam no ponto da Mediatriz (perpendicular bisector) que cruza o segmento $\overline{CD}$.

Voltando: Scalene Triangle ΔABC. (I)

No triângulo escaleno (scalene triangle) ΔABC, ou seja, os 3 lados deste triângulo apresentam diferentes tamanhos.

Na hipótese, em que realizamos a mediatriz, utilizando-se "perpendicular bisector" do segmento em questão, como por exemplo, $\overline{AB}$, $\overline{BC}$ e $\overline{AC}$.

No triângulo escaleno, os três lados de um triângulo são diferentes, mas ao fazer a "perpendicular bisector" de cada lado do triângulo, nós obteremos os seguintes pontos F, D, E, que farão partes de 3 triângulos equiláteros.

Análise:

a) Triângulo escaleno (scalene triangle) → ΔABC.

b) "Perpendicular bisector" (mediatriz) criar os seguintes triângulos equiláteros:

b1) Segmento $\overline{AB}$ cria-se o ponto F. Obteremos ΔABF (equilátero)

b2) Segmento $\overline{BC}$ cria-se o ponto D. Obteremos ΔBCD (equilátero)

b3) Segmento $\overline{AC}$ cria-se o ponto E. Obteremos ΔACE (equilátero)

c) No caso do ΔABF, ao realizarmos as mediatrizes dos respectivos lados do triângulo equilátero (perpendicular bisector), concluiremos que:

c1) A mediatriz de um lado é igual a bissetriz do ângulo oposto ao segmento em que se fez a mediatriz, constituindo-se "perpendicular barycenter".

Explicando: No triângulo equilátero as mediatrizes (perpendicular bisector) correspondem à "perpendicular barycenter", pois o "barycenter" se obtém ligando-se o "middle point" com o ângulo oposto, dividindo-se este ângulo ao meio.

Importante: No triângulo escaleno (scalene triangle), as mediatrizes dos segmentos $\overline{AB}$, $\overline{BC}$ e $\overline{AC}$ são

obtidas no ponto diferente do ponto "scalene barycenter", que no caso é o ponto x, enquanto o outro ponto é o y.

c2) Ao realizarmos as mediatrizes do triângulo equilátero ΔABF, obtemos o ponto K, este ponto é a intersecção dos 3 bissétores dos ângulos ABF.

A distância entre o ponto K e o ponto "scalene barycenter" é igual aos outros 2 triângulos equiláteros ΔBCD e ΔACE.

d) No caso do ΔBCD, ao realizarmos as mediatrizes dos referidos segmentos $\overline{BC}$ $\overline{BD}$ e $\overline{CD}$, ou seja, "perpendicular bisector", obtemos na intersecção destes segmentos o ponto Z.

A distância entre $\overline{xz}$ é igual aos segmentos $\overline{Kx}$ e $\overline{Wx}$.

e) No caso do ΔACE, ao realizarmos as mediatrizes dos referidos segmentos $\overline{AC}$, $\overline{AE}$ e $\overline{CE}$, ou seja, "perpendicular bisector", obtemos na intersecção destes segmentos o ponto W.

A distância entre $\overline{xW}$ é igual aos segmentos $\overline{Kx}$ e $\overline{Zx}$.

Estudar (não sei se é aplicável a todos os triângulos escalenos).

O segmento $\overline{BC}$ tem 6 cm, ao ligarmos os pontos K, W, Z ao ponto x, obteremos 3 segmentos com o mesmo comprimento: $\overline{xZ}$, $\overline{xW}$ e $\overline{xK}$ com 3 cm cada um, mas testes devem ser feitos

com outros comprimentos de reta, que no caso é o segmento BC (número par), fazer com número ímpar 7 etc)

It shows up, that the symmedian point K (= X6) is the Frégier point of the center of the Kiepert hyperbola (= X115) with respect to the Steiner inellipse.

Reversely said:

Is the Frégier point the symmedian

point K with respect to the Steiner inellipse, then the "Ex-Frégier point" is the center of the Kiepert hyperbola (= X115).

Análise:

a) Center of the Kiepert hyperbola.

20231015 0900

Kiepert Hyperbola is a hyperbola and triangle conic that is related to the solution of Lemoine's problem and its generalization to isosceles triangles constructed on the sides of a given triangle.

The vertices of the constructed triangles are given in trilinear coordinates by

$$A' = -\sin\phi : \sin(C+\phi) : \sin(B+\phi)$$
$$B' = \sin(C+\phi) : -\sin\phi : \sin(A+\phi)$$
$$C' = \sin(B+\phi) : \sin(A+\phi) : -\sin\phi$$

where ϕ is the base angle of the isosceles triangle.

Kiepert (1869) showed that the lines connecting the vertices of the given triangle and respondig peaks of the isosceles triangles concur.

Obs: Concurrent → two or more lines are said to be concurrent if they

intersect in a single point. Two lines concur if their <u>trilinear coordinates</u> satisfy

$$\begin{vmatrix} l_1 & m_1 & n_1 \\ l_2 & m_2 & n_2 \\ l_3 & m_3 & n_3 \end{vmatrix} = 0$$

Three lines concur if their <u>trilinear coordinates</u> satisfy

$$l_1\alpha + m_1\beta + n_1\gamma = 0$$
$$l_2\alpha + m_2\beta + n_2\gamma = 0$$
$$l_3\alpha + m_3\beta + n_3\gamma = 0$$

in which case the point is

$$m_2 n_3 - n_2 m_3 : n_2 l_3 - l_2 n_3 : l_2 m_3 - m_2 l_3.$$

Three lines are concurrent if their coefficients satisfy

$$\begin{vmatrix} A_1 & B_1 & C_1 \\ A_2 & B_2 & C_2 \\ A_3 & B_3 & C_3 \end{vmatrix} = 0.$$

Trilinear Coordinates:

Given a reference triangle ΔABC, the trilinear coordinates of a point P with respect to ΔABC are an ordered triple of numbers, each of which is proportional to the directed distance from P to one of the side lines.

Trilinear coordinates are denoted $\alpha : \beta : \gamma$ or (α, β, γ) and also are known as <u>homogenous coordinates</u> or "<u>trilinears</u>".

Trilinear coordinates were introduced by Plücker in 1835.

Since it is only the ratio of distances that is significant, the triplet of trilinear coordinates obtained by multiplying a given triplet by any nonzero constant describes the same point, so

$$\alpha : \beta : \gamma = \mu\alpha : \mu\beta : \mu\gamma.$$

For simplicity, the three polygon vertices, A, B, and C of a triangle are commonly written as

$1:0:0$, $0:1:0$, and $0:0:1$, respectively.

Trilinear coordinates can be normalized so that they give the actual directed distances from P to each of the sides.
To perform the normalization, let the point P in the above diagram have trilinear coordinates $\alpha : \beta : \gamma$ and lie at distances a', b', and c' from the sides BC, AC, and AB, respectively.
Then the distances $a' = k\alpha$, $b' = k\beta$, and $c' = k\gamma$ can be found by writing Δ_a for the area of ΔBPC, and similarly for Δ_b and Δ_c.

We then have
$$\begin{aligned}\Delta &= \Delta_a + \Delta_b + \Delta_c \\ &= \frac{1}{2}aa' + \frac{1}{2}bb' + \frac{1}{2}cc' \\ &= \frac{1}{2}(ak\alpha + bk\beta + c\beta\gamma) \\ &= \frac{1}{2}k(a\alpha + b\beta + c\gamma) \text{ so}\end{aligned}$$

$$K \equiv \frac{2\Delta}{a\alpha + b\beta + c\gamma}$$

where Δ is the area of ΔABC and a, b, and c are the lengths of its sides
(Kimberling 1998, pp. 26-27).

Book: (ref.)

Kimberling - "Central Points and Central Lines in the Plane of a Triangle"
Math. Mag. 67, 163-187, 1994.

Kimberling - "Triangle Centers and Central Triangles"
Congr. Numer. 129, 1-295, 1998.

To obtain trilinear coordinates giving the actual distances, take $K=1$, so we have the coordinates
$a' : b' : c'$.

These normalized trilinear coordinates are known as <u>exact trilinear coordinates</u>.

The trilinear coordinates of the line

$$ux + vy + wz = 0$$

are $u : v : w = a d_A : b d_B : c d_C$,

where d_i is the point-line distance from polygon vertex i to the line.

obs: Point-Line Distance – 2 Dimensional

The distance between a point with exact trilinear coordinates $(\alpha', \beta', \gamma')$ and a line

$l\alpha + m\beta + n\gamma = 0$ is

$$d = \frac{|l\alpha' + m\beta' + n\gamma'|}{\sqrt{l^2 + m^2 + n^2 - 2mn\cos A - 2nl\cos B - 2lm\cos C}}$$

(Kimberling 1998, p. 31)

M. U. S.

Anotar:

6) Symmedian Point:

In geometry, the Lemoine point, Grebe point or symmedian point is the intersection of the three symmedian (medians reflected at the associated bisectors) of a triangle.

Symmedian Point

The point of concurrence K of the symmedians, sometimes also called the Lemoine point (in England and France) or the Grebe point (in Germany).

Symmedians

Symmedians are three particular lines associated with every triangle. They are constructed by taking a median of the triangle (a line connecting a vertex with the midpoint of the opposite side), and reflecting the line over the corresponding angle bisector (the line through the same vertex that divides the angle there in half).

The angle formed by the symmedian and the angle bisector has the same measure as the angle between the median and the angle bisector, but it is on

the other side of the angle bisector.

Important:

a) No triângulo ΔABC, ao fazermos os ângulos bisectors, nós encontraremos um ponto I (concur at the incenter)

b) Ao fazermos no mesmo triângulo ΔABC, as medianas (Medians), nós obtemos o ponto G (concur at the centroid)

Medians → line connecting a vertex with the mid point of the opposite side.

c) No mesmo triângulo, ao fazermos a reflexão (reflecting) da mediana obtemos Symmedians (concur at the symmedian point L) que se interceptam no ponto L.

The three symmedians meet at a triangle center called the Lemoine point.

Ross Honsberger has called its existence

"one the crown jewels of modern geometry".

Chapter 7: The Symmedian Point. (1995)

→ Episodes in Nineteenth and Twenty Century Euclidean Geometry (1995).

Voltando (return):

Symmedian Point

~~Hos~~
Honsberg 1995, p. 76

The symmedian point lies on the Brocard axis (the Brocard axis is the line K O passing through the symmedian point K and circumcenter O of a triangle where the segment OK is the Brocard diameter (Kimberling 1998, p. 150).

The Brocard axis is perpendicular to the Lemoine axis and is the isogonal conjugate (the isogonal conjugate X^{-1} of a point X in the plane of the triangle ΔABC is constructed by reflecting the lines AX, BX, and CX about the angle bisectors at A, B, and C. The three

reflected lines then concur at the isogonal conjugate (Honsberger 1995, pp. 55–56).

(... Brocard axis is perpendicular to the Lemoine axis and is the isogonal conjugate of the Kiepert hyperbola.)

... The symmedian point lies on the Brocard axis and the Fermat axis. (Fermat axis is the central line connecting the first and second Fermat points. It has line function

$$l = a(b^2-c^2)(a^2-b^2-bc-c^2)(a^2-b^2+bc+c^2)$$

corresponding to trimedian center.

Obs: 1) First Fermat Point

The first Fermat point X (or F_1) (sometimes simply called "the Fermat point", Torricelli point, or first isogonic center) is the point X which minimizes the sum of distances for A, B, and C in an acute triangle,

$$|AX| + |BX| + |CX|.$$

It has equivalent triangle center functions

$$\alpha_{13} = \csc\left(A + \frac{1}{3}\pi\right)$$

$$\alpha_{13} = bc\left[c^2a^2 + (c^2+a^2-b^2)^2\right]$$
$$\left[a^2b^2 - (a^2+b^2-c^2)^2\right]$$
$$\left[4\Delta - \sqrt{3}\,(b^2+c^2-a^2)\right]$$

and is Kimberling center X_{13} (Kimberling 1998, p. 67).

<u>obs</u>: It also arises in Napoleon's theorem.

<u>obs) 2</u>: Second Fermat Point

The second Fermat point X' or F_2 (also known as the <u>second isogonic center</u>) can be constructed by drawing <u>equilateral triangles</u> on the inside of a given triangle and connecting opposite vertices. The three diagonals in the figure then intersect in the second Fermat point, which has triangle center function

$$\alpha = \csc\left(A - \frac{1}{3}\pi\right)$$ and is

Kimberling center X_{14}. (141
⇒ Kimberling 1998, p. 68).

Return:

... The symmedian point lies on the Brocard axis and the Fermat axis. It lies of the Brocard circle and is the center of the cosine circle. It also lies on the Jerabek hyperbola (The Jerabek hyperbola is a circumconic that is isogonal conjugate of the Euler line. (Kimberling 1998, p. 237).

↳ see:

Euler line (The line on which the orthocenter H, triangle centroid G, circumcenter O, de Longchamps point L, nine-point N, and a number of other important triangle center lie)

Obs: Longchamps point (L) is the reflection of the orthocenter H about the circumcenter O of a triangle. It has triangle center function

$$\alpha = \cos A - \cos B \cos C,$$

and is Kimberling center X_{20} (Kimberling 1998, p. 70).

<u>return</u> : <u>Euler Line</u>

... The Euler Line is perpendicular to the Lorychamps lines and orthic axis.

<u>return</u> : <u>Symmedian Point</u>

... It also lies on the Jerabek hyperbola and the <u>thomson cubic</u>.

(the Thomson cubic of (X_2) of a triangle $\triangle ABC$ is the <u>locus</u> the center of circumconics whose normals at the vertices are concurrent. It is a <u>self-isogonal cubic</u> with <u>pivot point</u> at the triangle centroid, so its parameter is $x = 6r$ and its trilinear equation is given by

$$6r\alpha(\beta^2+\gamma^2)+ca\beta(\gamma^2-\alpha^2)+ab\gamma(\alpha^2-\beta^2)=0$$

(Cundy and Parry 1995; Kimberling 1998, p. 240).

It is sometimes called the

seventeen-point cubic
(Casey 1893, p. 460;
Kimberling 1998, p. 240).

<u>return</u>: <u>Symmedian Point</u>

Its distances from K to the sides of the triangle are

$$KK_i = \frac{1}{2} a_i \tan\omega.$$

where
ω is the Brocard angle.

<u>Análisi</u>:

c) <u>Steiner point</u> (Fregier theorem → Heiss.)

<u>obs</u>: Steiner Circle
is the central circle with center at the nine-point center X_5 and radius

$$R_5 = \frac{3}{2} R,$$

where R is the <u>circumradius</u>
(the circumradius of a cyclic polygon is a radius of the circle inside which the polygon can be inscribed. Similarly, the circumradius of a polyhedron is the radius of a

circumsphere touching each of the polyhedron's vertices, of such a sphere points).

return: Steiner Circle

It is the circumcircle of the Steiner deltoid.

Steiner Points:

there are (at least) three different types of points known as Steiner points.

The point S of concurrence of the three lines drawn through the vertices of a triangle parallel to the corresponding sides of the first Brocard triangle is called the Steiner point (Honsberger 1995).

It lies on the circumcircle opposite the Tarry Point T and has equivalent triangle center functions

$$\alpha = bc(a^2-b^2)(a^2-c^2)$$

$$\alpha = \frac{1}{a(b^2-c^2}$$

obs: It also lies on the Steiner circumellipse.
It is Kimberling center X_{99}.
The Brianchon point
(the point of concurrence of the joins of the vertices of a triangle and the points of contact of a conic of the triangle (Veblen and Young 1938, p. 111); Eddy and Fritsch 1994))

For, the Kiepert parabola is also the Steiner point (Eddy and Fritsch 1994).
The symmedian point K is the Steiner point of the first Brocard triangle (Honsberger, 1995, pp. 120-121).

The Simon Line (Importantissimo)
↳ Research.

The Simson Line is the line containing the feet P_1, P_2, and P_3 of the perpendiculars from an arbitrary point P on the circumcircle of a triangle.

This line was attributed to Simson by Poncelet, but is now frequently know as the Wallace-Simson line since it does not actually appear in any work of Simson (Johnson 1929, p. 137; ~~Coxeter a~~ Coxeter and Greitzer 1967, p. 41; de Guzmán 1999).

Inverse statement:

The locus of all points P in the plane of a triangle $\triangle ABC$ such that the feet of perpendiculars from the three sides of the triangle is collinear is given by the circumcircle of $\triangle ABC$, is sometimes called the Wallace-Simson theorem (de Guzmán, 1999).

Important: The Simson line bisects the line HP, where H is the orthocenter (Honsberger, 1995, p.46).

Moreover, the midpoint of HP lies on the nine-point circle (Honsberger, 1995, pp. 46-47).

The Simson lines of two opposite point on the circumcenter of a triangle are perpendicular and meet on the nine-point circle (also called Euler's circle or the Feuerbach circle, is the circle that passes through the perpendicular feet H_A, H_B and H_C dropped from the vertices of any reference triangle ΔABC on the side opposite them.

Euler showed in 1765 that it also passes through the midpoints M_A, M_B, M_C of the sides of ΔABC.

By Feuerbach's theorem, the nine-point circle also passes through the midpoints E_A, E_B and E_C of the segments that joint the vertices and the orthocenter H. These points are commonly referred to as the Euler points. ✡

These three triples of points make nine in all, giving the circle its name.

It shows up that the symmedian point K (= X6) is the Frégier point of the center of the Kiepert hyperbola (= X115) with respect to the Steiner inellipse.

Reversely said:

Is the Frégier point the symmedian point K with respect to the Steiner ellipse, then the "Ex-Frégier point" is the center of the Kiepert hyperbola (= X 115).

O texto é longo mas de um modo geral, todos estes pontos serão úteis para manter a integridade dos cálculos, mas aplicável à uma superfície curva.

De acordo com o avançar da pesquisa, estes pontos serão projetados de forma ortogonal sobre uma superfície curva ou serão descritos na própria superfície curva.

Eu não preciso de tantos referenciais para fundamentar a minha pesquisa. O que interessa é comprovar a nova mudança de paradigma pois de um ponto de vista objetivo, os cálculos estão equivocados em virtude de terem sido obtidos com base em superfície plana.

Source: https://triangle-geometry.jimdofree.com

Importante:

Usar estes pontos como referencial para se manter a consistência dos gráficos, mas o que interessa é a lógica global do objetivo que se pretende obter.

Devemos unir estes conceitos com Ligne Droite - Papelier e posteriormente vincular com o livro:

Sortais - La géométrie du triangle - Exercices résolus - (1997).pdf

Return to Frégier theorem

Fig. 02 → Frégier point S and Ellipse (or another conic section).

Neste exemplo, nós precisamos começar com uma ellipse e depois calcular o ponto S. (Frégier Point), posteriormente, nós inserimos os círculos.

Com esta representação, nós conseguimos interligar 2 círculos com tamanhos (raio) diferentes com uma ellipse.

<u>Important</u>:

Poncelet's closure theorem → also know as Poncelet's porism, states that whenever (a quelquer momento) a polygon is one conic section and circumscribes another one, the polygon must be part of an infinite family of polygons that are all inscribed in and circumscribe the same two conics.

Conic Section: The conic sections are the nondegenerate curves generated by the intersections of a plane (~~perpendicular~~) with one or two nappes of a cone.
For a plane perpendicular to the axis of the cone, a circle is produced.
For a plane that is not perpendicular to the axis and that intersects only a single nappe, the curve produced is either an ellipse or a parabola (Hilbert and Cohn-Vossen 1999, p.8)
The curve produced by a plane intersecting both nappes is a hyperbola (Hilbert and Cohn-Vossen 1999, pp.8-9).

return: Poncelet's Porism →

Hyperbola (Gray 1997, p. 45) is a conic section defined as the locus (a locus is the set of all points (usually forming a curve or surface) satisfying some conditions. The locus of points in the plane equidistant from a given point is a circle, and the set of points in three-space equidistant from a given point is a sphere)

... locus of all points P in the plane the difference of whose (cujo) distances $r_1 = F_1P$ and $r_2 = F_2P$ from two fixed points (the foci F_1 and F_2) separated by a distance $2c$ is a given positive constant k,

$$r_2 - r_1 = k$$

(Hilbert and Cohn-Vossen 1999, p. 3)

Letting P fall on the left x-intercept requires that

$$k = (c+a) - (c-a) = 2a$$

so the constant is given by $k = 2a$.

Important: Rectangular hyperbola →

The special case of the rectangular hyperbola corresponding to a hyperbola with eccentricity $e = \sqrt{2}$, was first studied by Menaechmus.

IMPORTANT:

The hyperbola is the ~~sp~~ shape of an orbit of a body on an escape trajectory (i.e., a body with positive energy), such as some comets, about a fixed mass, such as the sun.

Obs:

i.e. (id est) → "that is"

e.g. (exempli gratia) → "for example"

Return: conic section (Important)

Kepler was the first to notice that planetary orbits were ellipses

(Ellipse is a curve that is the locus of all points in the plane the sum of whose distances r_1 and r_2 from two fixed points F_1 and F_2 (the foci) separated by a distance of $2c$ is a given positive constant $2a$ (Hilbert and Cohn-Vossen 1999, p. 2).

This results in the two-center bipolar coordinate equation

$r_1 + r_2 = 2a$.

→ major radius

where a is the semimajor axis and the origin of the coordinate system is at one of the foci.

The corresponding parameter b is known as the semiminor axis.

↳ minor radius

The ellipse is a conic section and a Lissajous curve.
(parametric curve)

return: KEPLER was first to notice that planetary orbits were ellipses, and Newton was then able to derive the shape of orbits mathematically using calculus (?), under the assumption that

gravitational force

goes as the inverse square of distance.

IMPORTANT:

CONIC SECTION may more formally be defined as the locus of a point P that moves in the plane of a fixed point F called the focus and a fixed line d called the ...

... conic section directrix (is the line which, together to define a conic section as the locus of points whose (unjo) distance from the focus is proportional to the horizontal distance from the directrix, with

(with F not on d) such that the ratio of the distance of P from F to its distance from d is a constant e called the eccentricity

r being the constant of proportionality.

If the ratio:

r = 1, the conic is a parabola,

r < 1, it is an ellipse, and

r > 1, it is a hyperbola.

(Hilbert and Cohn-Vossen 1999, p. 27)

return: ... called the eccentricity.

If e = 0, the conic is a circle,

If 0 < e < 1, the conic is an ellipse,

If e = 1, the conic is a parabola, and

If $e > 1$, it is a hyperbola.

A conic section with <u>conic section directrix</u> at $x=0$, focus at $(p, 0)$, and <u>eccentricity</u> $e > 0$ has Cartesian equation

$$y^2 + (1-e^2)x^2 - 2px + p^2 = 0$$

(Yates 1952, p. 36), where p is called the <u>focal parameter</u>

Plugging in p gives

$$y^2 + (1-e^2)x^2 - \frac{2a(1-e^2)}{e}x + \frac{a^2(1-e^2)^2}{e^2} = 0,$$

for an <u>ellipse</u>,

$y^2 = 4a(x-a)$, for a <u>parabola</u>, and

$$y^2 + (1-e^2)x^2 - \frac{2a(e^2-1)}{e}x + \frac{a^2(e^2-1)^2}{e^2} = 0$$

for a <u>hyperbola</u>.

<u>Eff</u>: the polar equation of a conic section with focal parameter p is given by

$$r = \frac{pe}{1 + e\cos\theta}.$$

Return: Poncelet's Porism

Poncelet Transverse

Let a C_1 lie inside another circle C_2. From any point on C_2, draw a tangent to C_1 and extend it to C_2.

From the point, draw another tangent etc. For n tangents, the result is called an n-sided Poncelet transverse.

If, on the circle of circumscription there is one point of origin for which a four-sided Poncelet transverse is closed then the four-sided transverse will also close for any other point of origin on the circle (Dörrie 1965).

Obs: If the conic is taken as a circle (Casey 1888, pp. 124-126), then a polygon which has both an incenter and a circumcenter

(and for which the transversals would therefore close) is called a <u>bicentric polygon</u>.

(A polygon which has both a circumcircle (which touches each vertex) and a incircle (which is tangent to each side).

All triangles are bicentric with

$$R^2 - x^2 = 2Rr,$$

where R is the circumradius, r is the inradius, and x is the separation of centers.

For bicentric quadrilaterals, a result sometimes known as <u>FUSS'S problem</u>, the circles satisfy

$$2r^2(R^2 + x^2) = (R^2 - x^2)^2$$

(Dörrie 1965, Salazar 2006) or, in another form,

$$\frac{1}{(R-x)^2} + \frac{1}{(R+x)^2} = \frac{1}{r^2}$$

(Davis; Durège 1861; Casey 1888, pp. 109–110; Johnson 1929; Dörrie 1965).

Important:

Para estabelecer parâmetros para a minha pesquisa, nós devemos observar os seguintes ~~pa~~ aspectos:

a) constant of proportionality:

$r = 1 \rightarrow$ parabola,

$r < 1 \rightarrow$ ellipse, and

$r > 1 \rightarrow$ hyperbola.

b) constant e (eccentricity)

$e = 0$, the conic is a circle,

$0 < e < 1$, the conic is ellipse,

$e = 1$, the conic is parabola, and

$e > 1$, the conic is hyperbola.

Frégier Ellipses

We introduce Frégier ellipses as generalization of the Frégier point and exhibit amazing angles and areas invariants.

IMPORTANT:

Utilizar esta invariabilidade para se manter os ângulos e as áreas invariáveis nos cálculos de projeção da superfície curva sobre um plano ortogonalmente. Antes da projeção estes cálculos servem para manter a consistência dos cálculos e na projeção haverá uma alteração nestes valores.

20231017172800

20231017214242

Solução para calcular a curvatura do espaço sobre a órbita elíptica dos planetas. (Uma delas). Estudar com profundidade.

Eu fiquei pensando em uma forma metódica para calcular a curvatura gerada pelas forças fundamentais do Universo sobre as órbitas elípticas e eu irei usar os mesmos procedimentos utilizados para análisar uma órbita elíptica.

A 2ª elipse estará no eixo z, mas com um tamanho menor

obs: Usaremos a parte inferior da elipse (curvatura)

obs: Importante
2 elipses:
a) Plano x e y)
b) Plano - z
(curvatura sobre o plano x e y).

Esta 2ª elipse será projetada (sobre) de forma ortogonal sobre um plano para o cálculo do novo número Pi (M.U.S.)

Vejamos, nós teremos 3 coordenadas de valores números referentes à elipses, ou seja, x e y com a elipse orbital de um corpo celeste e z, ou seja, no eixo z mas com valor negativo em virtude da curvatura do espaço.
A obtenção destes 3 valores usarão as mesmas regras da elipse:
a) constant of proportionality
b) constant e (eccentricity)
<u>Obs</u>: A 2ª elipse terá um valor menor pois trata-se da curvatura do espaço.
<u>Important</u>: O valor negativo no eixo z poderá ser representada por uma equação que represente aquela curvatura.
Esta curvatura abrange toda a elipse da órbita do corpo celeste e a projeção ortogonal sobre um plano permitirá o cálculo do novo número do Pi (M.U.S.).
<u>Important</u>: Este aspecto será de fundamental importância para a checagem dos cálculos obtidos, pois devemos utilizar este mecanismo nas <u>duas elipses</u> (x e y) e (z → -z).
Primeiro, devemos escolher um ponto P sobre a elipse (x, y) e obter <u>Frégier Point</u> (S) e a partir do ponto P, nós deveremos criar <u>dois círculos</u> que se

intercepta no ponto P. (círculos diferentes)

Não se esqueça de marcar os dois centros dos círculos (M_1 e M_2), pois estes pontos serão utilizados para marcarmos dois segmentos, ambos passando pelo ponto S, criando-se assim o segmento ou reta que passa pelos pontos SM_1 e SM_2, sendo que ambos os segmentos estarão contidos nos respectivos círculos de tamanhos diferentes, M_1 círculo menor e M_2 círculo maior.

Important:

a) SM_1 e SM_2 devem ter o mesmo tamanho do diâmetro dos seus respectivos círculos.

b) SM_1 e SM_2 deverão atingir a elipse em ambos os pontos do segmento.

Interessante:

Eu tive uma idéia interessante, e se nós criarmos os dois círculos cujos dois pontos de intersecção fiquem justamente sobre a elipse em que nós obtemos o ponto Finder Point (S) a partir do ponto P.

O primeiro ponto é o ponto P ale atário sobre a elipse.

O segundo ponto sobre a elipse

é o **ponto Musich (M_e)**, ou seja,

M_e = Musich elipse.

Desta forma, nós teremos mais um referencial de checagem dos cálculos. Vejamos:

Alinhar os pontos Me_1 S e M_2, and Me_3

Important: Alinhar os pontos P M_1 S e Me_2

obs: Este é um tipo de configuração que eu criei. (checar com cuidado!!!)

off: No primeiro exemplo, os dois círculos não tem tanta convergência (colineas) dos pontos.

Nós podemos observar que:

SM_1 tem o diâmetro do primeiro círculo e as duas extremidades (estão) do segmento estão sobre o círculo, mas não está sobre nenhum ponto de intersecção entre os círculos. Observamos que somente o ponto P é uma intersecção entre os dois círculos M_1 e M_2, mas não está sobre o outro ponto Me.

O segmento que passa pelos pontos S M2 tem o diâmetro (acabou a caneta) do círculo M2 e as duas extremidades estão sobre a elipse.

Obs: Checar os pontos Me1, Me2 e Me3.
↳ Musick point.

Interessante:

Os pontos:

a) P M1 S Me2 → é uma reta com 4 pontos.

b) Me1 S M2 Me3 → é uma reta com 4 pontos

Obs: São duas retas para dar maior consistência aos cálculos e com o ponto Me1 (Musick point) nós teremos uma maior estabilidade nos cálculos entre os dois círculos e estas duas retas (checar os cálculos).

20231017231700 Stff

20231018153500

Construção Geométrica da Elipse utilizando-se régua e compasso:

- Trace o eixo maior
- Extremidades são os vértices A e A', marcando os focos F e F' e o centro O.

A partir de F e F', trace arcos de tamanhos iguais marcando os pontos 1, 2, 3 e 4 e 1', 2', 3' e 4', ajuste de acordo com a reta

Agora, com a ponta seca do compasso em F e (arcos ou raios) F1', F2', F3'... e depois com centro em F' e arcos F'1, F'2, F'3... trace os arcos. IMPORT: Compasso A1', depois mova para F e trace arco F'. *

obs.: Estes procedimentos sempre no segmento $\overline{AA'}$.

Com centro em F e raios A1, A2, A3... e depois com centro em F' e raios A'1', A'2', A'3'..., trace arcos de modo a interceptarem os primeiros.

A curva que passa pelos intersecções e pelos vértices A e A' é a elipse de centro O e focos F e F'.

O segmento de reta ortogonal ao eixo AA' que passa pelo centro O, é o eixo

menor, cujas extremidades são as intersecções com a elipse formando seus vértices B e B'.

Important:

Neste exemplo, a base desta elipse é o Focus, ou seja, a sua unidade de medida. Nós devemos ajustá-la para adequá-la à realidade de nossa pesquisa.

Construção: 10 unidades ou 12 unidades.

obs. O segmento A3' quando em F traça o arco em 2 (A2). 3 e 3' ficam de fora.

obs. (Com relação aos pontos 3 e 3', podemos o ponto A → A3' e A' → A'3.)
→ wrong
muda-se a curvatura

Neste caso, erros na realização do arco em 3 e 3', e ainda F. (Ficar atento!!)

Important:

O segmento A A' deve estar contido numa reta maior para que possamos traçar os arcos de forma correta. Havendo mais pontos de referência, melhores serão os resultados.

Nova construção na próxima página:

Segmento com 14 unidades:

A0 em F traça o arco A3' e A'0 em F' traça o arco A'3. (*)
Na intersecção dos arcos 3 e 3', obtemos 2 pontos B e B' (reta ortogonal)

Important
A distância entre AF e A'F' é uma unidade que nós poderemos ajustá-la para adequar-se à excentricidade da referida elipse.

Segunda Forma de Construção de uma Elipse.

A construção desta elipse depende de seus dois eixos.

Important: Ajustando-se estes 2 eixos, nos teremos a excentricidade. (calcular depois) (4)

Descrevemos dois círculos de centro O com diâmetros iguais aos eixos AA' e BB'.

Dividimos a circunferência maior e menor em N partes iguais. Por conveniência, nós vamos dividi-las em 16 partes iguais, realizando-se as bissetrizes entre os eixos e depois repetimos o processo.

Em seguida, traçamos retas perpendiculares ao eixo AA' pelos pontos que dividem a circunferência maior. (1)

Depois, traçamos retas perpendiculares ao eixo BB' pelos pontos que dividem a circunferência menor. (2)

Os pontos (x_n, y_n) gerados a partir das intersecções destas retas determinam a elipse.

Aumentando as retas da elipse:

B3, B4, B5 e B6 → são as primeiras bissetrizes.

C1, C2, C3 e C4 → são os pontos que interceptam o círculo maior.

D1, D2, D3, D4, D5, D6, D7 e D8 → são as novas bissetrizes.

Ligues os pontos: D1D5, D2D6, D3D7, D4D8, criando-se os seguintes pontos: E1, E2, E3, E4, E5, E6, E7 e E8.

(círculo maior) e os pontos: B, BB1, BB2, BB3, BB4, BB5, BB6, BB7, B', BB8, BB9, BB10, BB11, BB12, BB13 e BB14 (círculo menor).

Ligue os seguintes pontos:

E2 E3
C1 C3
E1 E4
E5 E8
C2 C4
E6 E4

círculo maior
(linhas azuis)
→ tracejadas.

BB7 BB8
BB6 BB10
BB5 BB11
BB3 BB12
BB2 BB13
BB1 BB14

círculo menor
(linhas vermelhas)
→ tracejadas.

As intersecções entre as linhas azuis e as linhas vermelhas delimitam ou determinam a elipse.
Os referidos pontos são:

B
B$\underline{\text{I}}$, B$\underline{\text{II}}$, B$\underline{\text{III}}$
A
B$\underline{\text{IV}}$, B$\underline{\text{V}}$, B$\underline{\text{VI}}$
B'
B$\underline{\text{VII}}$, B$\underline{\text{VIII}}$, B$\underline{\text{IX}}$
A'
B$\underline{\text{X}}$, B$\underline{\text{XI}}$, B$\underline{\text{XII}}$

pontos que determinam a elipse.

<u>Obs</u>: Fazer estas 2 simulações do ponto de vista antrético.

Important:

Estas construções foram feitas utilizando-se régua e compasso de forma gráfica e com erros e imprecisões nas definições dos referidos pontos que determinam a elipse.

Agora, nós devemos fazê-lo de forma analítica, calculando-se os pontos e as suas distâncias, as bissetrizes devem ser obtidas por meio da determinação do ponto (x, y) que dividem cada quadrante da elipse.

Tudo tem que ser demonstrado de forma inequívoca.

20231018183700

20231018210000

A título de informação científica, complementar ao que eu já venho estudando eu encontrei na internet https://zenodo.org/records/1447218, a publicação com o título:

"Signal Time Travel Dilation TEM Model Time Machine Creation Theory 10/04/2018

→ Lance E. Wenner

Nome do arquivo:

Wenner-Time-Dilation-Ref-10-04-2018.pdf

Obs: Estudar com Tony Yuan 7-2.pdf (Gravitational Waves).

Gravity Time Length Well

Light (electromagnetic wave time path bending) while passing near a large mass like a Planet is also a time dilation effect rather that light speed change, which is again against Einstein [1], or some other invisible unknow lensing medium in the vacuum of space. ⊛

A mass warps the time length of its surrounding space an amount progressively more the larger the mass within limites per Einstein GR [1].

Tensor Calculus of momentum pressure in GR general relativity of the EINSTEIN [1] dual (4x4) matrix equation includes the fourth dimension time energy.

Ref.: 1) Synge - Tensor Calculus - (1949).pdf
→ 334 pages.

2) The Geometry of Total

Curvature on Complete open surfaces - 2003.pdf
→ Katsuhiro Shiohama...
→ 296 pages.
Obs: Pág. 41 — chapter 2
the classical results of Cohn-Vossen and Huber
↳ referência:

Hilbert, D. and Cohn-Vossen, S, "The Cylinder, the Cone, the Conic Sections, and their surfaces of Revolution".

3) The Geometry of Four-Manifolds-1997.pdf
→ Donaldson / Kronheimer
→ 458 pages.
Obs: Usar este livro para analisar fourth dimension time energy.

return: Pág. 6

This demonstrates all curved path space-time gravity (all earth size gravity for example) is mostly time length well charge effect (time dilation).

Increasing the mass increases the stress-energy tensors, hence bending its space-time curve path more (other mass taking less time length to arrive) thereby, due to the smaller time arc at same distance reducing geodesic path length of the other mass heading somewhat toward it (not attraction but falling more toward larger mass in less time).

A time length well theory for Earth gravity does therefore not violate general relativity but agrees with and its effective limits of, very large mass bending actual 3d space, more than 4d time, once becoming a very large size like a neutron star.

IMPORTANT:

→ LESS ENERGY ⊛

Less Energy → see Entropy.

Since taking less time, mass or light (EMW) ⊛

$\boxed{\text{use less energy}}$

following a space-time curved space (takes more energy to turn away), ⊛ therein not violating the conservation of energy Newton [4] law either.

Velocity time length special relativity (SR) change is a different time dilation mode from general relativity (GR) gravity time length change.

(SR) Increased velocity dilates time longer,

(GR) increased mass dilates objects heading toward it time shorter, both within the limits of Minkowski [8] 4 dimensional space-time for SR and GR.

Pág. 09 – Fig. (13) →

Waveguide delay time formula vs. Einstein SR vacuum Earth length compared indicating similar time curve relations. Confirms time delay per frequency in a

angular waveguide.

Fig. (14) Demonstrates the surfaces trackness (to reflect off) and their waveguide effect to delay wavelengths at different time intervals which in fact splits the light into different frequencies (wavelengths).

(*) The surface material determines the waveguides depth and angle of reflection required to obtain a full color light spectrum. (ver Newton → sobre o seu trabalho sobre as cores).

IMPORTANT: In an equilateral triangle the shape distance keeps all the different output light frequencies arriving at the same time called in phase. In other shapes, glass time delays light, rather than (em vez de) falsely bending or changing light speed etc again as previously discussed.

20231018231200 [illegible]

20231022133000.

Arquivo: ellipse-20231022-01.ggb

Roteiro de criação

1) Crie os seguintes pontos:

a) F1 = Point (x Axis)
→ (-4, 0)

b) F2 = Point (x Axis)
→ (4, 0)

c) A1 = Point (x Axis)
→ (-5, 0)

d) A2 = Point (x Axis)
→ (5, 0)

e) A = Point (y Axis)
→ (0, 3)

f) O = Intersect (x Axis, y Axis)
→ (0, 0)

obs: Important:

Esta configuração de pontos é muito interessante pois facilita os cálculos.

Vejamos: Os pontos focos F1 e F2 estão na posição (-4,0) e (4,0) e portanto, estão na posição de número par.

Usando-se o sistema cartesiano, mantendo-se uma unidade como padrão de distanciamento entre os pontos e para que os pontos A1 e A2 estejam mantendo a distância de uma unidade dos pontos focos F1 e F2, nós precisamos escolher o ponto A (y Axis) → (0, 3). Com este posicionamento nós criaremos uma elipse. O interessante, neste caso,

é que estamos realizando uma adequação entre os números pares (eixo x) e número ímpares (eixo y), observando-se o distanciamento de uma unidade como padrão.

Posteriormente, nós criaremos o ponto B (y Axis) → (0, −3)

2) Agora criaremos os círculos menor e maior com base no ponto O como origem e o diâmetro do tamanho dos retos A1A2 e AB.

Vejamos:

a) Círculo menor - AB

c : Circle(O, A)

→ $x^2 + y^2 = 9$

Obs: Important: Na aba de configuração do Geogebra chamada Style escolha: (se quiser)

1) Line Trickness: mínimo. 3

2) Line Opacity: mínimo. 20

b) Círculo maior

d : Circle(O, A2)

→ $x^2 + y^2 = 25$

Obs: 1) Line Trickness: 3

2) Line Opacity: 20

3) Em seguida, nós criaremos os pontos:

a) C = Intersect(d, y Axis, 2)

→ (0, 5)

b) D = Intersect(d, y Axis, 1)

→ (0, −5)

Vou ajustar para pontos em vez de intersecção pois facilita a escrita.

Portanto: Voltamos

Criando B = Point(y Axis)

→ (0 -3)

Em seguida, criaremos:

a) C = Point(y Axis)

→ (0 5)

b) D = Point(y Axis)

→ (0, -5)

Agora, nós criaremos os círculos:

a) Círculo menor:

c: Circle(O, A)

→ $x^2 + y^2 = 9$

b) d: Circle(O, C)

→ $x^2 + y^2 = 25$

Retornando um pouco

Criaremos os pontos:

a) E = Point(x Axis)

→ (-3, 0)

b) F = Point(x Axis)

→ (3, 0)

Agora (sim):

a) c: Circle(O, A)

→ $x^2 + y^2 = 9$

b) d = Circle(O, C)

→ $x^2 + y^2 = 25$

3) Nova Fase:

Angle Bisector → important.

Para nós criarmos Angle Bisector, nós poderemos fazer de duas formas!

a) Criaremos os pontos:

a1) G = Point(y Axis)
→ (0, 1)

a2) H = Point(x Axis)
→ (1, 0)

a3) I = (1, 1) ⇒ Point

↳ Aqui está o ponto que facilitará a construção.

Vejamos:

Criaremos

f: Line(O, I)
→ $-x + y = 0$

Obs: Esta é a função do 1º Quadrante.

Para agilizar:

Criaremos o ponto

J = (−1, 1)

Em seguida:

g = Line(O, J)
→ $-x - y = 0$

Obs: Esta é a função do 2º Quadrante.

Interessante:

O que foi feito facilita a construção da elipse.

Agora, vamos construir de outra forma, utilizando-se Angle Bisector, da seguinte maneira:

a) 1º Quadrante:

Voltando um pouco, nós criamos os pontos,

a1) G = Point(y Axis)
→ (0, 1)

a2) H = Point(x Axis)
→ (1, 0)

Após: Angle Bisector

b1) f: Angle Bisector(H, O, G)
→ $-0.707106781186547x + 0.707106781186547y = 0$

obs: Esta função é igual $-x+y=0$

b) 2º Quadrante:

Criamos o ponto I

I = Point(x Axis)
→ (−1, 0)

Em seguida: Caso mantenha o f(b1)

g: Angle Bisector(I, O, G)
→ $0.70710678...x + 0.70710678...y = 0$

Obs: Esta função é igual à

$$-x - y = 0.$$

Important:

Nós manteremos a versão mais simplificada, pois facilitará a didática para os futuros estudantes desta pesquisa e de matemática e física.

Em resumo:

Após a criação do círculo maior (0, C).

d : Circle (0, C)
$\rightarrow x^2 + y^2 = 25$

Nós criaremos, dois pontos:

a) O ponto $G = (1, 1)$
$\rightarrow$ que dividirá o 1º Quadrante.

b) O ponto $H = (-1, 1)$
$\rightarrow$ que dividirá o 2º Quadrante.

Em seguida, nós criaremos os linhas:

a) f: Line(O G)
$\rightarrow -x + y = 0$

b) g: Line(O H)
$\rightarrow -x - y = 0$

Obs: Desta forma os quatros quadrantes estão divididos ao meio.

Importantíssimo:

Antes de criarmos as linhas f e g, nós deveremos criar 4 pontos para ajudar na 2ª operação de Angle Bisector e são os seguintes:

a) $I = (3, 3)$

b) $J = (-3, 3)$

c) $K = (-3, -3)$

d) $L = (3, -3)$

Estudo Aprofundado:

Um aspecto interessante, com o ponto $I = (3, 3)$ nós dividimos o 1º Quadrante ao meio.

Para nós fazermos a próxima

Angle Bisector, primeiro vamos fazer um estudo mais detalhado:

Ponto F = Point (x Axis)
→ (3, 0)

Deste ponto, nós iremos (criara) criar um novo círculo

e: Circle (F, I)
→ $(x-3)^2 + y^2 = 9$

obs: antes disso, nós esqueço de criar o ponto

M = Point (x Axis)
→ (6, 0)

Depois de criar este ponto, nós criaremos o círculo e.

Em seguida, nós criaremos o segmento h

h = Segment (I, M)
→ 4.242640687119286

obs: Este segmento é $3 \times \sqrt{2}$!!! (interessante!!!)

IMPORTANTÍSSIMO.

O triângulo retângulo formado pelos vértices O I M Δ OIM, com ângulo reto em $\boxed{I}$, cujo catetos OI e IM são iguais, apresentando o mesmo comprimento $\boxed{3\sqrt{2}}$ e cuja hipotenusa $\boxed{\text{OM é 6 unidades}}$.

Atenção:

g: AngleBisector(F, O, I)
$\rightarrow 0.3826\ldots x + 0.9238\ldots y = 0$

Esta reta intersecta o cateto IM do triângulo retângulo Δ OIM, no ponto

$$\boxed{\begin{array}{l} N = \text{Intersect}(g, h) \\ \rightarrow (\underbrace{4.242640\ldots}_{(3\sqrt{2})\ \hookrightarrow x}, \underbrace{1.757359\ldots}_{\hookrightarrow y}) \end{array}}$$

Este novo triângulo Δ ONM,

que é um triângulo obtuso
e também é um triângulo escaleno
Ângulos:

$O = 22,5°$

$M = 45°$

$N = 112,5°$

<u>comprimentos</u>: Segmentos

O triângulo t_1

$t_1 = \text{Polygon}(M, O, N)$
$\rightarrow 5.2742077...$

<u>Segmentos</u>:

$m = \text{Segment}(O, N, t_1)$
$\rightarrow 4.5022011...$

$n = \text{Segment}(M, O, t_1)$ (M, O, t_1)
$\rightarrow 6$

$o = \text{Segment}(N, M, t_1)$
$\rightarrow 2.485281...$

<u>Portanto</u>: Triângulo escaleno
com ângulo obtuso.

Interessante:

O segmento

h = Segment (I, M) → comprimento
→ 4.242640...
(= 3√2)

e o ponto

N = Intersect (g, h)
→ 4.242640..., 9.757359...)
(x) (y)

este valor é igual ao segment (I, M)
(3√2)

obs: Os comprimentos são diferentes.
ON > IM.

IMPORTANTÍSSIMO:

Partindo-se do Ponto N (?), cujo valor não é exato.

N = Intersect (g, h)

Nós iremos traçar uma Perpendicular Line no ponto A2,

i: Perpendicular Line (A2, x Axis)
→ x = 5

obs: Este passo desvendará nos caminhos.

Esta perpendicular irá interceptar

$$\boxed{\begin{array}{l} f: \text{Line}(O, G) \\ \rightarrow -x + y = 0 \end{array}}$$

no ponto P

P = Intersect(f, i)
$\rightarrow (5, 5)$

Obs: Criar este ponto quando da criação dos primeiros pontos.

Exemplos de pontos complementares (a serem construídos)

$P = (5, 5) \rightarrow$ 1º Quadrante

$Q = (-5, 5) \rightarrow$ 2º Quadrante

Obs: Estes dois pontos já dividem os 4 quadrantes, mas devemos marcar os outros 2 pontos para facilitar a construção.

$R = (-5, -5) \rightarrow$ 3º Quadrante.

$S = (5, -5) \rightarrow$ 4º Quadrante.

Continuando:

Após construirmos a perpendicular sobre o ponto A2 e marcarmos o ponto P = (5,5), este ponto intercepta tanto a linha f como a linha i.

<u>Obs</u>:

f: Line (O, G)
→ $-x + y = 0$

i: Perpendicular Line (A2, x Axis)
→ $x = 5$

<u>Portanto</u>: O ponto $\boxed{P = (5, 5)}$ pode ser obtido marcando-se este ponto no 1º Quadrante ou fazendo-se a intersecção da linha f com a linha i (perpendicular ao ponto A2 no eixo x).

<u>Posteriormente</u>:

Marcamos o ponto:

T = Intersect (g, i)
→ (5, 2.07106 78...)
(x) (y)

e o ponto

$\boxed{\text{U = Intersect (i, h)} \rightarrow (5, 1)}$

☆

Importantíssimo:

U = Intersect(i, h)
→ (5, 1)

Obs: Este ponto deve ser marcado quando da criação dos primeiros pontos da construção.

Lembrando:

h = Segment(I, M)
→ 4.242640...
(3√2)
→ comprimento

Obs:

T = (3, 3)
M = (6, 0)

A interseção da linha i com a linha h e também com a linha g, criará um triângulo isósceles

(isosceles triangle)
invertido

Criaremos o triângulo ΔNTU

$t_1 = \text{Polygon}(N, T, U)$
$\rightarrow 0.40555315...$

$n = \text{Segment}(T, U, t_1)$
$\rightarrow 1.07100678...$

$t = \text{Segment}(U, N, t_1)$
$\rightarrow 1.07100678...$

$n = t$

$u = \text{Segment}(N, T, t_1)$
$\rightarrow 0.81197598...$

Obs: o Ponto $U = (5, 1)$, o ângulo interno de U é igual $45°$.

Important:
O triângulo $\Delta MAZU$ é um triângulo retângulo e a sua hipotenusa é $\boxed{\overline{UM} = \sqrt{2}}$

Obs:
$AZ\ M = 1$
$AZ\ U = 1$
$U\ M = \sqrt{2}$

Obs: Em um círculo com centro em $U = (5, 1)$, os pontos N e T estarão sobre o círculo.

Off:
$\text{Circle}(U, N) \rightarrow (x-5)^2 + (y-1)^2 = 1.147186...$

Obs: Se fizermos um círculo com centro $U = (5,1)$ e raio $A2 = (5,0)$

$\rightarrow (x-5)^2 + (y-1)^2 = 1$

Obs: Neste caso, os pontos N e T estarão fora do círculo.

Important:

Pontos:

$$\boxed{\begin{array}{l} I = (3,3) \\ U = (5,1) \end{array}}$$

A distância entre estes pontos é

$I = \text{Segment}(U, I)$

$\rightarrow 2.828427712...$

$= 2\sqrt{2}$

Nós devemos criar os seguintes pontos

$V = (1,5)$

$W = \text{Point}(y\ \text{Axis})$

$\rightarrow (0,6)$

Interessante: Vejamos $\rightarrow$

O Segmento (I, W)

$j = \text{Segment}(I, W)$
$\rightarrow 4.24264068\ldots$
$(= 3\sqrt{2})$

Preste atenção:

$k = \text{Segment}(N, I)$
$\rightarrow 1.757359\ldots$

Mas se nós somarmos

$\overline{UN} + \overline{NI} = \overline{UI}$

Obs: $I = \text{Segment}(U, I)$
$\rightarrow 2.8284271\ldots$
$(= 2\sqrt{2})$

Portanto:

$UN + NI = 2\sqrt{2}\ (UI)$

$IV = UI\ (2\sqrt{2})$

Obs: $\overline{UV} = 4\sqrt{2}$

Vamos prestar atenção.

Isto vai facilitar a minha pesquisa. $\rightarrow$

Fazendo AngleBisector do ângulo

A2 O T, nós obtemos

p: AngleBisector(A2, O, T)
→ 0.195090... x +
0.980785... y = 0

Obs: O mais interessante que o ponto exato que divide este ângulo e o ponto U

$$\boxed{U = (5, 1)}$$

WRONG!!!
Ajuda a dividir o ângulo

Important:

Não divide.

Este ponto (divide) o 1º Quadrante em 8 partes iguais e por consequente ~~também~~ divide o 3º Quadrante e o ponto é

Z = (−5, −1) → criar este ponto

Agora vamos ligar os ponto Z U

FILE: elipse-20231022-09.ggb.

p = Segment(Z, U)
→ 10.198039027...

20231022202233

20231023083000.

Esta fase de criação deste ponto será posteriormente!

$A_1 = (6, 4)$

$r = \text{line}(O, A_1)$

$\rightarrow -2x + 3y = 0$

<u>Retornando</u>:

Nós vamos criar os pontos dos outros quadrantes (2º, 3º e 4º).

Até este ponto (correto)

a) $A_1 = (-1, 5)$

b) $B_1 = (-5, 1)$

c) $C_1 = (5, 1)$

Estes pontos são referências para dividir os demais quadrantes (1/8 de um quadrante). (Ajudam)

Agora, nós iremos criar os outros pontos de referência:

(CHECAR)

a) $D_1 = (6, 4)$

b) $E_1 = (-6, 4)$

c) $F_1 = (-6, -4)$

d) $G_1 = (6, -4)$

Outras divisões nos quadrantes (2º, 3º e 4º) → 1/8 de um quadrante. (Ajudam) → checar!!!

Vamos continuar os divisões dos quadrantes:

Fazendo os "espelhamentos":

A) D_1 em relação P, obteremos o ponto $H_1 = (4, 6)$

Vejamos:

a) Ponto $P = (5, 5)$

b) Ponto $D_1 = (6, 4)$

c) Ponto $H_1 = (4, 6)$

Interessante:

A distância entre os pontos D_1P e PH_1 são iguais a $\sqrt{2}$.

Agora, nós vamos criar os outros pontos:

B) Ponto $J_1 = (-4, 6)$

obteremos:

a) $E_1 = (-6, 4)$

b) $Q = (-5, 5)$

c) $I_1 = (-4, 6)$

C) Ponto $J_1 = (-4, -6)$, nós obteremos:

a) $F_1 = (-6, -4)$

b) $R = (-5, -5)$

c) $J_1 = (-4, -6)$

D) $K_1 = (4, -6)$, nós obteremos:

a) $G_1 = (6, -4)$

b) $S = (5, -5)$

c) $K_1 = (4, -6)$.

Interessante:

Cada bloco destes 3 pontos, nós obteremos 2/8 de um quadrante.

Portanto:

a) $H_1 P D_1$ = 2/8 do 1º Quadrante;

b) $I_1 Q E_1$ = 2/8 do 2º Quadrante;

c) $F_1 R J_1$ = 2/8 do 3º Quadrante e

d) $G_1 S K_1$ = 2/8 do 4º Quadrante.

---

* Checar o ponto $U = (5, 1)$ → não divide o quadrante em 1/8. (11,30° → correto 11,25°)

Vamos checar os outros pontos:

Por exemplo: $D_1 P H_1$ →

Os pontos D_1 e H_1 estão errados.
Vamos criar outros mecanismos de checagem.

RETORNO:

Usaremos somente pontos precisos e não fazer Angle Bisector
↳ em números imprecisos.

correto.

Veremos:

Arquivo mais atualizado

ellipse-20231023-03.ggb

Novos Cálculos:

ellipse-20231023-04.ggb.

Paramos no ponto U

U = Intersect(i, h)
→ (5, 1).

Para confirmar a intersecção, criamos o ponto

Z = Intersect(h, i)
→ (5, 1).

Para ajudar nos cálculos:

Criaremos os pontos:

a) $A_1 = (-1, 5)$
b) $B_1 = (-5, 1)$
c) $C_1 = (-5, -1)$
d) $D_1 = (-1, -5)$
e) $E_1 = (1, -5)$
f) $F_1 = (5, -1)$

Estes pontos serão úteis para os cálculos de Angle Bisector.

Important:

Nós usaremos apenas Angle Bisector para dividir ao meio os 1º, 2º, 3º e 4º Quadrantes.

Vejamos:

$L = (3, -3)$
$I = (3, 3)$

criar uma linha ligando estes pontos.

$g_6 = \text{Segment}(L, I)$

Criar os seguintes pontos:

a) $H_1 = \text{Point}(d)$
$\rightarrow (4, -3)$

b) $I_1 = \text{Point}(d)$
$\rightarrow (4, 3).$

ligar estes pontos.

$r = \text{Segment}(H_1, I_1)$
$\rightarrow 6$

Vamos marcar os pontos sobre a elipse.

$J_1 = \text{Intersect}(p, q, 2)$
$\rightarrow (3, 2.4)$

$K_1 = \text{Intersect}(p, r, 2)$
$\rightarrow (4, 1.8)$

<u>continuando:</u>

$L_1 = \text{Intersect}(p, r, 1)$
$\rightarrow (4, -1.8)$

$M_1 = \text{Intersect}(p, q, 1)$
$\rightarrow (3, -2.4)$

Agora, nós vamos fazer o mesmo procedimento do outro lado (2º e 3º Quadrantes)

Os pontos:

$J = (-3, 3)$
$K = (-3, -3)$] > ligar estes pontos

$s = \text{Segment}(K, J)$
$\rightarrow 6$

$N_1 = \text{Point}(d)$
$\rightarrow (-4, 3)$

$O_1 = \text{Point}(d)$
$\rightarrow (-4, -3)$] > ligar estes pontos

$a = \text{Segment}(O_1, N_1)$
$\rightarrow 6$

$P_1 = \text{Intersect}(p, s, 2)$
$\rightarrow (-3, 2.4)$

$Q_1 = \text{Intersect}(p, a, 2)$
$\rightarrow (-4, 1.8)$

$R_1 = \text{Intersect}(p, a, 1)$
$\rightarrow (-4, -1.8)$

$S_1 = \text{Intersect}(p, s, 1)$
$\rightarrow (-3, -2.4)$

File de referência:

ellipse-20231023-05.ggb.

Criar o Frégier Point:

Crie o ponto T_1 sobre a elipse (ponto aleatório)

Crie outro ponto aleatório no outro lado da elipse: U_1

Após crie o segmento que ligue o ponto $U_1 T_1$.

Em seguida use o comando Perpendicular Line sobre o ponto T_1. Esta linha interceptará a elipse no outro lado, use o comando Intersect que unirá esta linha perpendicular à elipse.

Em seguida, crie uma linha que ligue (Segment) $V_1 U_1$ e em seguida marque o Polygon (T_1, U_1, V_1).

Neste momento, nós criamos o primeiro triângulo retângulo.

Para criar o segundo triângulo retângulo, nós devemos criar outro ponto:

W_1 sobre a elipse

Depois, com o comando Segment, ligar os pontos $T_1 W_1$.

Use o comando Perpendicular Line sobre esta linha no ponto T_1.

Esta linha intercepta a elipse no ponto Z_1, crie uma linha ligando os pontos W_1 e Z_1, marque um

Seguida o Polygon:
Polygon (T_1, W_1, Z_1).

Em seguida use o comando

Intersect em relação aos dois triângulos retângulos, criando-se assim, o ponto

Frégier Point (point D_2)

File: elipse-20231023-padrão-Frégier-Point.ggb.

Criação de 2 círculos que se interceptam sobre a elipse em 2 pontos:

Primeiro:

Crie a linha D_2T_1, sendo D_2 o ponto Frégier Point.

I_1: Line (D_2, T_1)
$\rightarrow -4.1342...x + 0.924011...y = -4.61...$

Após crie o ponto que intercepta esta linha com a elipse no ponto
(H_2 = Intersect (p, I_1, 2)
$\rightarrow$ (0.44923... , -2.987866).
Agora, partiremos para CIRCLE

Use o comando:

$\boxed{\text{Circle through 3 Points}}$

Ligando os seguintes pontos:

a) c_1: Circle (T_1, H_2, Z_1)

$\rightarrow (x - 1.0888275\ldots)^2 + (y + 0.0863965\ldots)^2 = 8.827609\ldots$

b) d_1: Circle (T_1, W_1, Z_1)

$\rightarrow (x + 0.7275995\ldots)^2 + (y + 0.4830656\ldots)^2 = 16.9682784\ldots$

Important:

Os 2 círculos se cruzam em 2 pontos (T_1 e Z_1) sobre a elipse.

Obs: Checar se os livros correspondem aos diâmetros dos referidos círculos.

File:

ellipse-20231023-10.ggb.

Off: Calcular os centros destes círculos com geometria e fazer simulação somente sobre estes círculos e livros, analisando os seus alinhamentos.

20231023 183200

20231024083000

Estudo sobre dois círculos que se interceptam em dois pontos e o ponto Frégier Point:

Agora: 20231024163100:

Simulei das 0830 às 1631 e obtive o arquivo:

ellipse-20231024-06-dois-circulos-MAIS-PROXIMO---3X3-PONTOS.ggb

Obs: Descrevê-lo posteriormente.

Ponto: J

J = Interseção (f, Eixo x)
→ (1.76, 0)

Este ponto é interessante (estudar)

Obs: O interessante desta simulação é que o ponto H e K há a interseção de 3 figuras geométricas.
- 2 círculos
- 1 elipse

Do outro lado, há também a interseção do círculo maior com a elipse.

Veja outro arquivo:
ellipse-20231024-06-dois-circulos-MAIS-PROXIMO---3X3-Pontos-Ponto1-76.ggb

Continuar as simulações dos dois círculos.

20231024175600

20231025081800

Eu criei uma forma de unir dois círculos que se interceptam em dois pontos e os quatro pontos criados que correspondem aos dois diâmetros destes dois círculos estão sobre a elipse.

Passos para criar esta simulação

obtida na data de 20231025120000 estes passos estão armazenados no arquivo:

Ellipse-20231025-01-2-circulos-ellipse-07.ggb

Source: Data-Novo Vivo-010-2023/ Geogebra-2023.

Obs: Estes últimos quatro dias foram de intensa pesquisa com o uso de computador.

Passos de criação:

1) A = Intersect(x Axis, y Axis)
→ (0, 0)

2) I = Point(x Axis)
→ (-8, 0)

3) J = Point(x Axis)
→ (8, 0

4) B = Point(y Axis)
→ (0, 6)

5) D = Point(y Axis)
→ (0, -6)

6) c: Ellipse(I, J, B)
→ $9x^2 + 25y^2 = 900$

7) C = Point(c)
→ (3.94..., 5.51...)
obs: Este ponto é aleatório e será utilizado para a criação dos dois triângulos retângulos para a obtenção do ponto Frejier Point

8) f: Perpendicular line (I, x Axis)
→ $x = -8$
obs: no ponto I (foci I), line through I perpendicular x Axis

9) Intersect (c, f)
→ E = (-8, -3.6)
→ F = (-8, 3.6)
obs: Estes dois pontos intersectam a perpendicular sobre a elipse

10) g = Segment (E, C)
→ 15.026...

11) h: Perpendicular (C, g)
→ 11.94...x - 9.11...y = -97.404...

12) G = Intersect (c, R, 2)
→ (9.533..., -1.8109..)
obs: Perpendicular sobre o ponto C e interrupta a elipse c.

13) i = Segment (E, G)
→ 17.62464...

14) j = Segment (F, C)
→ 12.190070...

15) K: Perpendicular (C, j)
→ -11.94...x - 1.912...y = -57.713...

16) H = Intersect (c, K, 2)
→ (5.624..., -4.96..)

17) I = Segment (F, H)
→ 16.090947...

18) K = Intersect (i, 1)
→ (1.857..., -2.594...)

obs: Este ponto K é o Fermat Point.

19) m : Line (C, K)
→ 8.10...x - 2.03009...y = 20.48333999...

20) L = Intersect (g, 1)
→ (2.82401..., 0.3476..)
obs: Dispensável mas tem um valor referencial.

21) M = Intersect (c, m, 2)
→ (0.98..., -5.97..)

22) Com o comando CIRCLE THROUGH 3 POINTS criaremos
d: Circle (C, H, M)
→ $(x - 2.1477118...)^2 + (y + 0.14655060...)^2 = 35.26702036...$

Important:
O Ponto C é um ponto aleatório.
O Ponto H é a perpendicular sobre o ponto C do segundo triângulo.

Este ponto H também intercepta a elipse c.

INCRÍVEL:

Este ponto H fazendo-se um segmento até o ponto K (Frégier Point)

Usando-se o segmento CM que é o diâmetro do primeiro círculo e usando-se a função Perpendicular Bisector,

nós descobrimos o centro deste círculo no ponto que esta perpendicular intercepta o segmento CM.

Obs: Para checar se é mesmo o centro, eu utilizei o sistema das duas cordas sobre o círculo, eu fiz Perpendicular Bisector destas duas cordas e elas se encontraram no mesmo ponto.

Outro jeito é usando um compasso para marcar a perpendicular sobre este segmento.

Portanto:

23) n: Perpendicular Bisector(M, C)
→ $-2.9606\ldots x - 11.4832\ldots y = -4.67\ldots$

24) N = Intersect(m, n)
→ $(2.4676\ldots, -0.22903\ldots)$

25) e: Circle(N, C)
→ $(x - 2.4676\ldots)^2 + (y + 0.2290\ldots)^2 = 35.1578\ldots$

Importantíssimo:

Com este círculo nós podemos eliminar o círculo anterior (C, H, M) → criado por meio dos três pontos, ou seja, este novo círculo (N, C) encontra ou intercepta a elipse em dois pontos

$\boxed{C \text{ e } M}$

Portanto, há 4 pontos na mesma linha (colineares)
→ $\boxed{C, N, K \text{ (Origin Point) e } M}$

Obs: O Ponto H quando ligado ao Ponto K (Origin Point), encontra o ponto F ("foci") que a perpendicular sobre o foci I (−8, 0).

26) p: Circle(F, H, C)
→ $(x + 1.187723\ldots)^2 + (y + 0.680483\ldots)^2 = 64.72964422\ldots$

27) g: Perpendicular Bisector(F, H)
→ $-13.62455\ldots x + 8.5609663\ldots y = 10.35661077\ldots$

28) O = Intersect(g, l)
→ $(-1.187723\ldots, 0.68048\ldots)$

Source:

Elipse-20231025-01-2-circulos-e-elipse-07.ggb

Important:

O segmento:

a) CM = diâmetro do primeiro círculo (menor)

b) FH = diâmetro do segundo círculo (maior)

Important:

4 pontos em cada linha (colineares)

a) C N K M,

b) F O K H.

obs!!! Estou feliz!!! Eu tive a benção de DEUS.

Voltando aos estudos de 20231017

Os pontos C (aleatório) e K (Frégier Point) são padrões desta simulação.

Agora, os pontos

a) H → é o ponto Me1.

b) M → é o ponto Me2.

c) F → é o ponto Me3.

Obs: Me = Musich Ellipse

Importante:

Me1, Me2 e Me3 → estão intimamente relacionados com os diâmetros dos círculos na elipse.

Desta forma, cada diâmetro apresenta 4 pontos:

a) Círculo Menor: CNKM.

b) Círculo Maior: FOKH.

Obs: Esta é a primeira fase da

Simulação das órbitas elípticas dos planetas sobre a curvatura do espaço.

Obs: Calcular a curvatura do espaço no nosso sistema solar.

Pág. 539(548) - Historical Remarks on Gauss-Bonnet.

Let M be a two-dimensional oriented Riemannian manifold and D a compact domain on M bounded by a sectionally smooth curve C. The Gauss-Bonnet formula says:

$$\sum (\pi-\alpha) + \int_C K_g \, ds + \iint_D K \, dA = 2\pi \chi(D)$$

where $\chi(D)$ is the Euler characteristic of D and the members at the left-hand side are respectively the exterior angles at the corners, the integral of the geodesic curvature, and the integral of the Gaussian curvature.

These are respectively the point, line, and surface curvatures, so that the formula expresses the total curvature in

terms of a topological invariant.

The most important special case of the formula is the theorem on the angle sum of a rectilinear triangle in the euclidean space.

Pág. 548 (557) – What is Geometry?

IMPORTANT:

Pág. 549 (558) –

Euclid realized that the PARALLEL POSTULATE was not as transparent as his other axioms and postulates.

Efforts were made to prove it as a consequence.

Their failure led to the discovery of non-Euclidean geometry by C. F. GAUSS, John Bolyai, and N. I. Lobachevski in the early 19th century.

Pág. 551 (560) →

A fundamental notion is "CURVATURE" in its different forms. Its simplest manifestation

is the circle in plane Euclidean geometry.

(1) IMPORTANT: O problema está no círculo pois este é representado de forma equivocada. Tanto no plano euclidiano como no "não-plano" euclidiano, nós observamos uma inconsistência matemática.

Nós devemos adequá-los à uma nova realidade que se impõe, ou seja, estas figuras geométricas devem ser reescritas de acordo com os novos parâmetros estabelecidos pela nova Matemática e consequentemente, a uma nova geometria que se faz presente com a readequação dos princípios matemáticos antigos aos novos, estabelecidos pelo

M. U. S.

→ Mathematical Uniform Space.

Uma nova matemática para uma nova realidade, realidade esta antiga e até agora, desconhecida pelo mundo da Matemática antiga.

Retornando:

... Euclidean geometry.

It would also be the force of a physical system or the strength of a gravitational or electro-magnetic field.

Obs: Estudar em conjunto com o item 32 de anterior, livro: "About the Biggest, the Smallest and Everything..." pdf (gravity → off)

Pág. 59 (90) → Coulomb's Experiments.

⇒ Relação de forças entre as estruturas.

In mathematical terms it measures the non-commutativity of covariant differentiation.

It is remarkable that suitable algebraic combinations of curvature give topological invariants.

To illustrate this we wish to state the

Gauss-Bonnet theorem.

Let D be a domain with a sectionally smooth boundary on a two-dimensional Riemannian manifold.

Then the Gauss-Bonnet theorem is

the formula

$$\sum (\pi - \alpha) + \int_{\partial D} K_g \, ds + \iint_D K \, dA = 2\pi \chi(D),$$

obs: Checar a fórmula correta na página 539 (548) →

Pág. 55 — Lemma 1.

Let $X(u,v)$ be an <u>orthogonal parametrization</u> of a neighborhood on an oriented surface S in $\mathbb{R}^3$, and let $W(t)$ be a smooth field of unit vectors along the curve

$\alpha(t) = X(u(t), v(t))$ on S.

Then

$$[DW/dt] = \frac{1}{2}(EG)^{-\frac{1}{2}} \{ G_u \, dv/dt - E_v \, du/dt \} + d\varphi/dt,$$

where $\varphi(t)$ is the angle from X_u to $W(t)$ in the given orientation.

d) The Gauss-Bonnet theorem
→ 10 pages.

Pág. 5 → Definition 3.5.

The geodesic curvature K_g of a curve is a measure of the amount of deviance of the curve from the shortest arc between two points on a surface.

Definition 3.6.

The Gaussian curvature K of a surface is an intrinsic measure of the curvature of a surface at a point.

<u>Retornando</u>:

$$\sum (\pi - \alpha) + \int_{\partial D} K_g \, ds + \iint_D K \, dA = 2\pi \chi(D),$$

where the first term is the sum of the exterior angles at the corners, the second term is the integral of the geodesic curvature along the sides, the (third) third term is the integral of the Gaussian curvature over D, and $\chi(D)$ is the Euler characteristic of D.

Pdg. 553 (562) –

The above provides the geometrical basis of gauge field theory in physics.

Here M is a four-dimensional Lorentzian manifold, so that the Hodge $*$-operator is defined, and we define the codifferential

$$\delta = * d *$$ (17)

M.U.S.

There is discrepancy of terminology and notation, as given by the following table:

mathematics	physics
connection ω	gauge potential A
curvature Ω	strength F

Maxwell's theory is based on a $U(1)$-bundle over M, and his field equations can be written

$$dA = F, \quad \delta F = J, \qquad (18)$$

where J is the current vector.
Actually, Maxwell wrote the first equation as

$$\mathcal{L} F = 0, \qquad (19).$$

which is a consequence.

Alexandrov-Intrinsic Geometry of Convex Surfaces-2005/

a) Alexandrov-Selected Works Part I..-1996.pdf

Pág. 01(12)- Chapter I

On Infinitesimal Bending of Nonregular Surfaces

→ 1936

Study of continuous length-preserving deformations

of a surface is sensible not only for regular surfaces.

It suffices that on a surface there be enough curves for which the concept of length is meaningful.

Lebesgue defined the corresponding class of the so-called rectifiable surfaces (la famille des surfaces rectifiables) as follows.

A surface S, (4)

$$x = f(u,v),\ y = \varphi(u,v),\ z = \psi(u,v)$$

given over a domain D in the plane (u,v) is said to be rectifiable, if to each rectifiable curve on D there corresponds a rectifiable curve on S.

IMPORTANT:

For a surface homeomorphic to a $\boxed{\text{sphere}}$,

we naturally take a sphere of unit radius as the domain of parameters. Then, every

(CONVEX) $\boxed{\text{Convex surface}}$ is rectifiable, as seen if a sphere in the interior of the surface is mapped onto it in (de intro dele) sulla (en tal) a way that a point of the sphere is sent to the point on the surface lying on the same radius.

a) 20231028 - Posamentier -
The Secrets of Triangles
A Mathematical Journey - (2012).pdf

Pág. 128 - The angle bisector not only bisects the angle, it also partitions the opposite side proportionally to the two adjacent sides. That is, for FIGURE 5-3, we have AD as the bisector of angle BAC, which then gives us

$$\boxed{\frac{c}{b} = \frac{m}{n}}$$

Figure 5-3

Pag. 129

To show why this is true is a bit tricky, as we must bring in some auxiliary lines:

We construct BE parallel to AD and intersecting CA (extended) at point E.

All the angles marked with $\frac{a}{2}$. are equal.

Therefore, since triangle AEB is isosceles, $AE = AB = c$.

For triangle BCE, we have

$$\frac{AE}{CA} = \frac{BD}{CD}, \text{ or } \frac{c}{b} = \frac{m}{n}.$$

While it is relatively easy to find the length of an altitude of a triangle (usually using the Pythagorean theorem), it is not so trivial to find the length of an angle bisector of a triangle.

There is a very helpful relationship that can be used to find the length of an angle bisector

Pag. 130 — In FIGURE 5-4, we have triangle ABC, with AD, the bisector of $\angle BAC$, which we will call t_a. We begin our

development by extending AD beyond D to meet the circumscribed circle of triangle ABC at E.

We then draw BE.

Since $\angle BAD = \angle CAD$, and $\angle E = \angle C$

(both angles inscribed in the same arc),

$\triangle ABE \sim \triangle ADC$, and

$$\frac{AC}{AD} = \frac{AE}{AB}, \text{ or}$$

$$AC \cdot AB = AD \cdot AE = AD(AD+DE) =$$

$$AD^2 + AD \cdot DE$$

However, $AD \cdot DE = BD \cdot DC$,

since they are intersecting chords of the same circle.

Substituting equation (II) into equation (I), we obtain

$$AD^2 = AC \cdot AB - BD \cdot DC,$$

which is what we sought to develop.

Yet in simpler terms, using the letter designations in

FIGURE 5-3, we can write this relationship as

$$t_a^2 = bc - m \cdot n, \text{ or}$$

$$t_a = \sqrt{bc - mn}$$

Figure 5-4

For the ambitious reader we provide yet another formula for finding the length of the angle bisector of a triangle given only the three sides:

$$t_a = \frac{2\sqrt{bcs(s-a)}}{b+c},$$

$$t_b = \frac{2\sqrt{cas(s-b)}}{c+a},$$

$$t_c = \frac{2\sqrt{abs(s-c)}}{a+b}, \text{ where}$$

$$s = \frac{a + b + c}{2}.$$

Curvilinear Coordinates

Gabriel Lamé (1795-1870) in his treatise: "Lecons sur les coordonnés curvilignes et leurs diverses applications" of 1859.

He used transformations to curvilinear coordinates in solving certain problems of heat conduction and elasticity.

Pág. 106 (118) – 7.3.2

Distance and Angle Measurements.

Obs.: Einstein pode ter se inspirado para analisar a curvatura do espaço.

Pág. 108 (120) –

Magnitude of the vector (7.41) is evidently given by

$$|v| = \sqrt{(v^\xi)^2 + (v^\eta)^2 + 2 v^\xi v^\eta e_\xi \cdot e_\eta} \quad (7.42)$$

Note the "cross term" above involving the scalar product of the basis vectors.

Important:

$\boxed{\text{ORTHOGONAL COORDINATE SYSTEM}}$

It is only in the special case of an Orthogonal coordinate system - ⊛ for which e_ξ and e_η are

$\boxed{\text{everywhere mutually perpendicular}}$

Obs: Estudar com profundida esta afirmação.

checar

⇒ Eu tenho as minhas dúvidas!!!

$\boxed{\text{Aprofundar com cautela!!!}}$

Cont. (retornando ao texto)

everywhere mutually perpendicular - ⇒ that this term is absent!

(the simplest example is, of course, Cartesian coordinates).

Similarly, given two vector $\boxed{u \text{ an } v}$ with curvilinear ~~Coordi~~ components

(u^ξ, u^η) and (v^ξ, v^η) at a prescribed point (ξ, η), we can form their dot product (product)

$$u.v = u^\xi v^\xi + u^\eta v^\eta + (u^\xi v^\eta + u^\eta v^\xi)\, e_\xi . e_\eta,$$

and thus determine the angle θ between them from

$$\cos\theta = \frac{u.v}{|u|\,|v|}, \qquad (7.43)$$

where $|u|$ is given in terms of (u^ξ, u^η) by an expressions analogous to (7.42).

We can also avoid the normalization (7.40) and use the metric tensor directly to compute angle between vectors: we replace the numerator in (7.43) by

$$[u^\xi, u^\eta] \begin{bmatrix} r_\xi . r_\xi, & r_\xi . r_\eta \\ r_\xi . r_\eta & r_\xi . r_\eta \end{bmatrix} \begin{bmatrix} v^\xi \\ v^\eta \end{bmatrix},$$

(R)

and similarly $|u|$ and $|v|$ are replaced by the square roots of the scalar values obtained by multiplying the metric on the left and right by the components of u and v, respectively.

Figure 8.28 illustrates lines of curvature on a "triaxial ellipsoid"

(all three semi-axes are of unequal length)

⇑ Obs:

checar a viabilidade de utilizar quando projetado ortogonalmente em um plano.

– in this case, the lines of curvature are all closed loops. They form an orthogonal net except at the umbilics situated on the section containing the smallest and largest semi-axes. These curves were first accurately drawn – in plane projection – by

Gaspard Monge in his 1807 treatise "Application de l'Analyse à la Géometrie".

...

– the surface "patches" delineated by the lines of curvature would ⇒ define the ~~sp~~ shapes of the roof tiles, and

he proposed that chandeliers be suspended from two umbilical points - see [367, p. 269].

The lines of curvature shown in Fig. 8.28 admit an elegant geometrical interpretation.

For constants a, b, c and three different instances

$$\lambda, \mu, \nu$$

(such that $0 < \lambda < c^2 < \mu < b^2 < \nu < a^2$)

of the parameter η in the equation

$$\frac{x^2}{a^2-\eta} + \frac{y^2}{b^2-\eta} + \frac{z^2}{c^2-\eta} - 1 = 0 \quad (8.100).$$

Pág. 197 (209) - Chapter 9

Algebraic Geometry

Hence, to describe an algebraic space curve, two polynomial equations

$g(x, y, z) = h(x, y, z) = 0$ in the three Cartesian coordinates (x, y, z)

must be specified.

But this simply amounts to formulating the space curve as the set of points common to the two surfaces

$g(x, y, z) = 0$ and

$h(x, y, z) = 0$ — i.e.,

as the intersection of those surfaces.

This fact incurs difficult theoretical issues, concerning the conditions under which two algebraic surfaces will intersect in a

$\boxed{\text{single "irreducible" space curve}}$,

or in a composite of such curves.

Gravitational instantons
→ space Einstein equations is a consistent background of the EFS model preserving certain fraction of the supersymmetry.
The field configuration is given by

$$ds^2 = \frac{dr^2}{1-\frac{a^4}{r^4}} + \frac{r^2}{4}\left(d\theta^2 + \sin^2\theta\, d\phi^2\right) + \frac{r^2}{4}\left(1-\frac{a^4}{r^4}\right)\left(d\psi + \cos\theta\, d\phi\right)^2,$$

$$F = \frac{2}{r^4}\left(e^3 \wedge e^0 + e^1 \wedge e^2\right) = \dot{F},$$

$$\phi = 0; \quad a = 0; \quad g_1 = g_2$$

with the above choice of background fields, the supersymmetry variations give the projector conditions,

$$(1-\gamma_5)\epsilon = 0, \quad (\alpha^3 + \dot{\alpha}^3)\epsilon = 0$$

With these projectors the killing spinor equations look really simple, namely,

$$\partial_\mu \epsilon = 0$$

So the killing spinors are independent of $\theta, \theta, \phi, \psi$.

<u>Because</u> of the twin supersymmetric conditions, the solution preserves

$\boxed{\frac{1}{4}}$ <u>of the supersymmetry</u>.

The Curvature of Space

Curvature and Intrinsic Geometry of a Surface in the Works of Euler.

By the curvature of a curve at a point we mean the limit of the ratio of the angle $\Delta\alpha$ between the tangents at the endpoints of an arc to the length Δs of that arc as the latter contracts to the point; that is, the limit

$$K = \frac{d\alpha}{ds} = \lim_{\Delta s \to 0} \frac{\Delta\alpha}{\Delta s}. \quad (8.1)$$

K is also the reciprocal of the radius of curvature at the point in question, that is, the radius of the

$\boxed{\text{osculating}}$ $\boxed{\text{circle}}$

at that point. (the osculating circle at a point P of a curve is defined as the limit of circles determined by three points on the curve as they tend to P).

Osculating → first ⇒ Leibniz

(1) Leibniz → "New reflections on the nature of the angles of tangency and osculating and their use in mathematical practice to replace complex figures with simpler ones → 1686

The concepts of the curvature of a curve and of the osculating (literally "kissing" from the Latin osculans) circle were already known to Leibniz. (1)

Leibniz also suggested the possibility of characterizing the curvature of a surface by means of an osculating sphere. (2)

(2) In a letter to Johann Bernoulli, dated July 29, 1698.

Euler → "Investigations of the curvature of surfaces" – 1767.

(Pag. 1-22 – vol. 28)

Euler called a normal section of a surface $z = f(x, y)$ perpendicular to the xOy plane a principal section. By varying the angle φ

between a normal section and the principal section Euler found that at each point of the surface there is a maximal radius of curvature f and a minimal radius of curvature g, that their planes are perpendicular to one another, and

Pág. 281 (293) →

that the connection between an arbitrary radius of curvature

$$r = r(\varphi)$$ and the

radii of curvature f and g is given

Fig. 101

by

$$\boxed{r = \frac{2fg}{f+g-(f-g)\cos 2\varphi}}$$

→ Maxwell's equations

Pág. 135(147) - Chapter 5
Relativity and Electrodynamics

5.1 - Lorentz Transformation

Since Maxwell's equations involve derivatives with respect to space and time, they are clearly dynamical laws!

... Galilean transformation

$$x = x' + v t', \quad (5.1)$$

Pág. 137(149) -

Lorentz in 1904 established the mathematical result that Maxwell's equations can be true in all inertial frames if they are connected to each other by what we now call the

Lorentz transformation

$$x = \gamma(x' + vt'), \quad (5.6)$$

$$y = y', \quad (5.7)$$

$$z = z', \quad (5.8)$$

$$t = \gamma\left(t' + \frac{v}{c^2}x'\right), \quad (5.9)$$

where

$$\gamma = \frac{1}{\sqrt{1 - v^2/c^2}} \quad (5.10)$$

Obs: Einstein pode ter deduzido desta equação.

Note that $x' = 0$, $t' = 0$ corresponds to $x = 0$, $t = 0$, implying that time is set to zero in both the frames at the instant when the origins of the two frames coincide.

The revolutionary implication of (5.9) was the time measured by different observers can be different.

a) Hartle - Gravity - An Introduction to Einstein's General Relativity - 2014.pdf
→ 549 pages.
Pag. 107 (108) - Chapter 6
Gravity as Geometry
Pag. 128 (126) - 6.5
Spacetime is curved
In the presence of a gravitational field, spacetime remains flat, but clocks run at a rate that is a factor $(1+\phi/c^2)$ diferent from their rates in empty spacetime, where ϕ is the gravitational potential at the location of the clock.
Clocks run faster where ϕ is positive and slower where ϕ is negative.

Pag. 126 (127) - 6.6.
Newtonian Gravity in Spacetime Terms
(Fixed Metric)

$$ds^2 = -\left(1+\frac{2\phi(x^i)}{c^2}\right)(c\,dt)^2 + \left(1-\frac{2\phi(x^i)}{c^2}\right)(dx^2+dy^2+dz^2) \quad (6.20)$$

Pág. 135(136) – Chapter 7
The Description of Curved Spacetime

$$ds^2 = -dt^2 + dx^2 + dy^2 + dz^2 \quad (7.1)$$

in the $c = 1$ units.

Pág. 137(138) – Box 7.1

The Penrose Diagram for Flat Space

Pág. 138(139) → 7.2 Metric

To describe a general geometry use a system of four coordinates, x^α, to label the points and specify the line element giving the distance, ds^2, between nearby points separated by coordinate intervals dx^α. That line element will have the form

$$ds^2 = g_{\alpha\beta}(x)\, dx^\alpha dx^\beta, \quad (7.8)$$

where $g_{\alpha\beta}(x)$ is a symmetric, position-dependent ① matrix called the metric.

Obs: ① When dealing with functions of the coordinates, we routinely use the abbreviations $f(x^\alpha)$, or $f(x)$, for $f(x^0, x^1, x^2, x^3)$ where there is no danger of confusion.

For example, the metric for flat spacetime in polar coordinates (7.4) is (WRONG!!!)

$$g_{\alpha\beta}(x) = \begin{array}{c} \\ 0 \\ 1 \\ 2 \\ 3 \end{array} \begin{array}{c} \begin{array}{cccc} 0 & 1 & 2 & 3 \end{array} \\ \begin{pmatrix} -1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & r^2 & 0 \\ 0 & 0 & 0 & r^2\sin^2\theta \end{pmatrix} \end{array} \qquad (7.9)$$

Diagonal metrics such as this can be specified more compactly by writing $g_{\alpha\beta}(x) = \mathrm{diag}(-1, 1, r^2, r^2\sin^2\theta)$.

Obs: Este cálculo está errado pois vocês estão descrevendo uma superfície plana (que não é plana) em coordenadas polares.

Pág. 445 (444) – Chapter 21
Curvature and the Einstein Equation

$$\begin{pmatrix}\text{a measure of local} \\ \text{spacetime curvature}\end{pmatrix} = \begin{pmatrix}\text{a measure of} \\ \text{matter energy density}\end{pmatrix} \qquad (21.1)$$

This relation, called the Einstein equation (or Einstein's equation), is field equation of general relativity in the way that Maxwell's equations are the field equations of electromagnetism.

Skew-Symmetric Linear Transformations and Electromagnetic Fields.

2.1. Motivation via the Lorentz Law

A charged particle in M is a triple (α, m, e), where (α, m) is a material particle and e is a nonzero real number called the charge of the particle.

Lorentz World Force Law (or Lorentz 4-Force Law) which expresses the rate at which the particle's world momentum changes at each point on the worldline as a

linear function of the particle's world velocity:

$$\frac{dP}{d\tau} = eFU, \qquad (2.1.1).$$

where

$U = U(\tau)$ is the particle's world velocity,

$P = mU$ its world momentum

and,

at each point, $F: M \to M$ is a linear transformation defined in terms of the classical "eletric and magnetic 3-vectors $\vec{E}$ and $\vec{B}$" at that point (2.1.1) is an abbreviated version of the <u>somewhat</u> (un pouco) more accurate and considerably more cumbersome (pesado)

$$\frac{dP(\tau)}{d\tau} = e F_{\alpha(\tau)}(U(\tau)),$$

where

$F_{\alpha(\tau)}$ is the appropriate <u>linear transformation</u> at $\alpha(\tau) \in M$.

Curves and Curvature

Parametrized Curves and Arc Length.

Pág. 114 (128) - Definition 3.2
⇒

Let $x : [a,b] \to \mathbb{R}^2$

be a parametrization of a curve C. Then the arc-length function on C is

$$s(q) = \int_a^q \|x'(q)\| \, dq.$$

... The differential ds is therefore

$$\boxed{ds = \left(\left(\frac{dx}{dq}\right)^2 + \left(\frac{dy}{dq}\right)^2 \right)^{1/2}}$$

$$\boxed{dq = \sqrt{dx^2 + dy^2}}$$

Obs: A distância será alterada em virtude da inclusão de novos parâmetros referentes à curvatura do espaço. As coordenadas serão alteradas para $\boxed{M.U.S.}$

Pág. 116 (130) — ellipse

Let us the arc-length parametrization of the ellipse

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1, \quad 0 < b < a$$

$\therefore K = \frac{\sqrt{a^2 - b^2}}{a}$ and

$0 < K = 1$

(ellipses have different proportions, and K is an index, or modulus, of shape.

If $\boxed{K = 0, \text{ then } a = b,}$ so the ellipse would be a circle.

As K increases, the ellipse denotes more and more from a circular shape; for this reason K is called the eccentricity of the ellipse).

Pág. 117 (131) —

Curvature of a Curve

Definition 3.3 $\longrightarrow$

Let $y(s)$ be the arc-length parametrization of the curve C. then we define:

unit tangent vector along C : $u(s) = \frac{dy}{ds}$;

curvature vector along C : $K(s) = \frac{du}{ds} = \frac{d^2y}{ds^2}$;

curvature at s: $K(s) = \|K(s)\|$.

Pág. 08(20) – 1.3
The Riemannian curvature tensor

Newton's first law states that the motion of a particle is in a straight line at constant speed if no force acts upon it.

Geodesics on a Riemannian manifold are understood to be subject to Newton's first law: it is considered that the straightness of a geodesic is equivalent to the existence of a parallel velocity vector field along it.

Lemma 1.3.1. Let $z(t) = \xi^i(t) X_i \circ \gamma(t)$ be a vector field along a curve γ, where $\gamma(t) = (x^1(t), \dots, x^n(t))$ in a coordinate neighborhood U. Then the map

$$t \mapsto \left(\frac{d\xi^i}{dt} + \Gamma^i_{kj}\,\xi^k \frac{dx^j}{dt}\right) X_i \circ \gamma(t)$$

is independent of the choice of local coordinates, and hence is a vector field along γ.

Pág. 166 (180) — parallel lines, which they used for the purpose of establishing by a general proof the proposition that the sum of the three angles of any triangle is equal to two right angles.

IMPORTANT:

Pág. 191 (205) - We resume Eudemus's account.

Pág. 193 (207) -

IMPORTANT:

A linha vermelha (concava) → negativa, apresenta uma curvatura.

Calcular esta curvatura.

A case too where the outer (exterior) circumference is less than a semicircle was solved by Hippocrates, who gave the following preliminary construction.

Let there be a circle with diameter AB, and let its centre be K.

Let CD bisect BK at right angles; and let the straight line EF be so placed between CD and the circumference that it verges towards B

[i.e. will, if produced, pass through B], while its

length is also such that the square on it is $1\frac{1}{2}$ times the square on (one of) the radii.

Let EG be drawn parallel to AB, and let (straight lines) be drawn joining K to E and F.

Let the straight line [KF] joined to F and produced meet EG in G, and again let (straight lines) be drawn joining B to F, G.

It is then manifest that BF produced will pass through ["fall on"] E [for by hypothesis EF verges towards B], and BG will be equal to EK.

Interessante:

Simplicius proves this at length. The proof is easy.

The triangles FKC, FBC are equal in all respects [Eucl, I. 4]. Therefore, EG being parallel to KB, the triangles EDF, GDF are equal in all respects [Eucl. I. 15, 29, 26]. (right triangles). Hence the trapezium is isosceles, and BG=EK.

this being so I say that the trapezium EKBG can be comprehended in a circle.

a) 20231102-A Course in Metric Geometry-2001.pdf
Pág. 07 (16) - 1.2.3. Spheres
Example 1.2.25. - The n-spheres S^n is the set of unit vectors in R^{n+1}, i.e., $S^n = \{x \in R^{n+1} : |x| = 1\}$.

The angular metric on S^n is defined by $d(x,y) = \arccos \langle x, y \rangle$.

In other words, the spherical distance is defined as the EUCLIDEAN ANGLE between unit vectors.

It equals the length of the shorter arc of a great circle connecting x and y in the sphere.

Another formula for this metric is

$$d(x,y) = 2 \arcsin \frac{|x-y|}{2}.$$

The metric on the circle described in Example 1.2.9 is a partial case of this example.

Pág. 04 (13) - Example 1.2.9. →
The unit circle, S^1, is the set of points in the plane lying at distance 1 from the origin.

Being a subset of the plane, the circle carries the restricted Euclidean metric on it. We define an alternative metric by setting the distance between two points as the length of the shorter arc between them.

For example, the arc-length distance between two opposite points of the circle is equal to $\boxed{\pi}$. → wrong!!!

Obs: Metric is wrong too!!!

The distance between adjacent vertices of a regular n-gon (inscribed into the circle is equal

$$\boxed{\frac{2\pi}{n}}.$$

Interessante: Exercise 1.2.10.

(a) Prove that any arc of length less or equal to π, equipped with the above metric, is isometric to a straight line segment.

(b) Prove that the entire circle with this metric is not isometric to any subset of the plane (regarded with the restriction of Euclidean distance onto this subset).

Pág. 03(12) – Example 1.2.3.

and Example 1.2.4.

$$|(x_1, y_1).(x_2, y_2)| = \sqrt{|x_1 x_2|^2 + (y_1 y_2)^2}$$

In particular, $R \times R = \mathbb{R}^2$.

Angle Sum and the Defect of a Triangle

Definition:

Let ΔABC be a triangle in a protractor (transferidor) geometry. The defect of ΔABC is

$$\boxed{\delta(\Delta ABC) = 180 - (m(\angle A) + m(\angle B) + m(\angle C)).}$$

We already know that for a EUCLIDEAN GEOMETRY

$$\boxed{\delta(\Delta ABC) = 0}$$

for all triangles $\boxed{\text{(Theorem 7.2.9)}}$

⇒ será estudado mais tarde.

We have seen examples in which

$$\boxed{\delta(\Delta ABC) < 0}$$

(the Moulton Plane)

and in which

$$\boxed{\delta(\Delta ABC) > 0}$$

(the Poincaré Plane)

We also know that for a neutral geometry

$$\boxed{\delta(\Delta ABC) \geq 0}$$

(Theorem 7.2.8).

IMPORTANT: GAUSS recognized that in order to prove EPP is satisfied it was sufficient to prove that $\boxed{\delta(\Delta ABC) = 0}$ for one triangle.

obs: EPP – Euclidean Parallel Property

Pág. 175(190) – See Figure 7-8.

Theorem 7.1.6.

If l is a line and $P \notin l$ in a neutral geometry which satisfies EFP (Euclid's Fifth Postulate), then there exists a unique line l' through P which is parallel to l.

Figure 7-8

obs: Since the 18th century the conclusion of Theorem 7.1.6. has been used as the primary parallel axiom.

Because this choice was first championed by Playfair, it is often referred to as Playfair's Parallel Postulate.

Pág. 181 (196) – Theorem 7.2.7.

In a neutral geometry the sum of the measures of the acute angles of a right triangle is less than or equal to 90.

Theorem 7.2.8 (Saccheri's Theorem)

In a neutral geometry, the sum of the measures of the angles of a triangle is less than or equal to 180.

Pág. 182 (197) –
Theorem 7.2.9
(Euclidean Angle Sum)
In a neutral geometry which satisfies EPP, the sum of the measures of the angles of any triangle is exactly 180.

See:

Figure 1.2. Region in Example 1.2.5.

Obs:

Example 1.2.5

Let R be the region in the xy-plane that lies in the first quadrant (that is, $x \geq 0$ and $y \geq 0$) and is between the hyperbolas $xy = 1$, $xy = 2$, and bounded by the lines $2y = x$, $y = 2x$

(see Figure 1.2),
Specify R by a set of inequalities.

Solution: The region in the first quadrant that is between the hyperbolas $xy=1$ and $xy=2$ is specified by the conditions that

$x>0$ and $1 \leq xy \leq 2$.

Similarly the region in the region in the first quadrant that is between the lines

$2y=x$ and $y=2x$ is

specified by the conditions that

$x>0$ and $1/2 < y/x \leq 1$.

Hence we see that $(x,y) \in R$ if and only if

$1 \leq xy \leq 2$ and $1/2 \leq y/x \leq 2$

and $x>0$.

Pág. 374 (395) –
The photon is an example of a massless relativistic particle with an energy, whose value depends on the reference frame.

Minkowski coordinates.

$$p^0 = \hbar \frac{\omega}{c}, \quad p^a = \hbar k^a, \quad a = 1, 2, 3$$

where $\omega > 0$ is the angular frequency of the particle's light wave and k^a are the three components of the

wave vector in the frame.

Above $\boxed{\hbar = \frac{h}{2\pi}}$ → wrong !!!,

Where h is Planck's Constant (6.626×10^{-27} erg sec).

As

$$\sum_{a=1}^{3} (k^a)^2 = \left(\frac{\omega}{c}\right)^2$$

from electromagnetism, in this case we must have $g(P, P) = 0$ and so the photon is massless and its world lines are lightlike.

Clearly there is no Minkowski frame at rest with a photon, because $k^a = 0$ for $a = 1, 2, 3$ would force $\omega = 0$ and the four-momentum would not be casual.

Sometimes one reads that photons are "pure energy".

Kaufmann's method

Kaufmann's experiments show that the real constant mass of the electron is negligible (insignificante) compared with the apparent [electrodynamic] mass; it can be considered as zero, so that if it is mass which constitutes matter we can almost say the matter no longer exists... there are merely holes in the aether.

Poincaré.

Pág. 152 (178)

Kaufmann found that e/m varied slightly with velocity, ~~descr~~ decreasing with increasing velocities.

$\boxed{\text{Fig. 3.7.}}$ the points on the parabola refer to electrons deflected by parallel and anti-parallel (left side) fields.

IMPORTANTÍSSIMO:

Pág. 153 (179) →

Ritz [08] (1911 - Gesammelte Werke - Oeuvres) queried the invariance of Kaufmann's parabola (3.7.17)

(3.7.17) - Kaufmann obtains the equation of a parabola

$$y = \frac{c^2 E}{\kappa H^2} \frac{m}{e} x^2 \qquad \text{Pag. 152 (178)}$$

the ratio,

$$\frac{y}{x} = \frac{c}{\mu} \frac{E}{H'} \qquad (3.7.18)$$

is, therefore, a measure of the deviation of the Lorentz force from zero [cf. Eq. (3.7.15) above].

... Kaufmann's parabola, (3.7.17), for it will only have that form if m is independent of the speed.

If the mass did increase with velocity, say, at some power greater than one, the parabola would tend to a straight line as that power increases.

Instead of (3.7.18) (as curves) Ritz tried (b)

$$\frac{y}{x} = \frac{\sqrt{(c^2 - \mu^2)}}{\mu} \frac{E}{H'} \qquad (3.7.19)$$

giving rise to a parabola,

$$y = \frac{mc^2 E}{eKH^2} x^2 + K \frac{eE}{mc^2}, \quad (3.7.20)$$

shifted upward at the origin.

(b) Actually, Ritz wrote 2c for c, but that does not change anything "in a theory which considers only relative velocities."

Pág. 341(367) – 7.1.

Centrifugal versus Gravitational Forces.

General relativity is based on the notion that gravity, rather than being a force acting between masses, is the curvature of space-time itself. The source of the (positive) curvature is mass it self, just like electric charge is the source. And just as free particles follow

"straight lines in space-time"

Obs: Do ponto de vista teórico, nós podemos representar matematicamente uma linha reta, mas isto não condiz com a realidade do Universo, pois caso o Universo tenha começado com o Big-Bang, não há possibilidade do Universo ser plano em virtude da energia inicial que por si só interfere na formatação do Universo.

Um aspecto interessante do Universo, ele não pode ser infinito em virtude do próprio Big-Bang. É uma questão de lógica, o finito não pode conter o infinito, pois se ele começou, não é infinito e para que ele exista há a necessidade do espaço, este sim infinito, o nada é infinito e em cima deste nada o Universo pode surgir, se desenvolver e se espandir.

Deus criou o nada para que o Universo pudesse surgir.

Se Deus tivesse preenchido tudo, não haveria a necessidade do surgimento do Universo.

O espaço é algo infinito e que alguns chamam de aether.

O espaço do nada permite a criação de tudo.

Deus é tão magnânimo que permitiu que algo fosse criado para receber o homem, ou seja, o Universo foi criado pela benevolência de Deus para que o homem pudesse viver nele. Quando eu digo o homem, eu me refiro à vida e há infinitas formas de vida no Universo.

Portanto, o Universo existe porque há o espaço do nada que

permite que o Universo se expanda.

↳ orbita dos planetas.

IMPORTANTISSIMO:

If we take a flat space metric in the plane and consider a constant index of refraction, we will demonstrate that Fermat's principle is capable of yielding the phase of the oscilation of a Bessel function of the first kind in the periodic domain in the asymptotic short-wavelength limit.

This is identical to the WKB result, and it allows us to associate a wave phenomenon with a geodesic trajectory.

The only potential present is the repulsive centrifugal potential, and that keeps the trajectory open.

Pág. 438 (464) - WKB

Expression (9.2.7) is the phase of the phase of the Hermite polynomials in the short-wavelength (WKB) limit. ... Planck's constant

Reformando: Pag. 342 (368) -
In contrast to the generalization of special relativity, where gravity is considered to be the curvature of space-time instead of a bona fide force, the centrifugal force is built into the phase of the Bessel function in the periodic domain where the trajectory consists of straight-line segments that are tangent to a caustic circle, whose radius is determined by the magnitude of the angular momentum
↳ (see book: 20231103 - Biedenharn - Angular Momentum in quantum physics - (1981). djvu).
and the arc segment joining the points of tangency.

Whereas expression (11.3.1a) corresponds to the xx-component of the Maxwell stress,

$$\sigma_{xx} = \frac{1}{8\pi}\left(E_y^2 - E_z^2\right),$$

Retornando: Search: bending

Pág. 343 (369) – The bending of light requires a coupling of the gravitational and centripetal potential that is commonly referred to as Schwarzschild's potential [cf. Fig. 7.6]. Here, it arises when we determine the extremum condition for Fermat's principle.

Pág. 448 (474) – The hyperbolic geometry that describes a uniformly rotating disc also describes the bending of light by a massive body when the transition is made from a constant to a non-constant surface of negative curvature.

Pág. 452 (478) – The geodesic still appear as straight lines to the Poincarites, whereas, to us Euclideans, they appear to be bent, and things vary in size depending on where we look. We also see things like the bending of light and the shifting of frequencies in a gravitational field.

Pág. 462 (488) – The bending of the geodesic is attributed to the rotation of the disc [Grøn 04]. But if the stereographic hyperbolic metric were applicable it would invalidate

Einstein's old result (9.6.16)

$\boxed{9.6.16}$ → Integrating over a period,

$$h = \frac{2\pi r}{\sqrt{(1-r^2/k^2)}} > 2\pi r \quad (9.6.16)$$

shows that the length of a hyperbolic circle of radius $\sinh(R/k)$ is greater than that (do we mean) of an Euclidean circle having a radius r [$= k \tanh(R/k)$]. this is none other Einstein's old results!!!

Retornando:

... (9.6.16), and it would also be in conflict with his general theory.

there is no way out for (9.6.28) to hold,

$\boxed{9.6.28}$ → Pag. 461 (487) -

The Euclidean area of the ellipse is

(interessante!!!)

$$\pi \frac{(1-r^2/K^2)^{3/2}}{K^2} = \frac{\pi}{K^2} \operatorname{sech}^3\left(\frac{\bar{r}}{K}\right).$$

↳ Wrong !!! (ajustar)

If we use the hyperbolic definition of an angular momentum

for the stereographic inner product model that we found previously in (9.2.5),

$$\ell_h = \frac{r^2 \dot{\vartheta}}{1-r^2/K^2}, \qquad (9.6.28)$$

then we must modify the equation for the radius of the trajectory,

$$\dot{r} = \pm c\left(1-\frac{r^2}{K^2}\right)\sqrt{\left[1-\frac{\Delta^2}{r^2}\left(1-\frac{r^2}{K^2}\right)\right]}, \qquad (9.6.29)$$

if and only if $\Delta = \ell_e/c$, where $\ell_e = r^2\dot{\vartheta}$, the Euclidean expression for the angular momentum.

Pág. 476 (502) - the curvature (9.10.11)

$\boxed{9.10.11}$, the curvature will be negative and constant. In general,

the curvature is

$$K = -T_0^2 \left(\frac{\lambda^2}{r_1^2} j_0^{2} + j_0'^{2} \right). \quad (9.10.11)$$

Retornando:

The curvature (9.10.11) cannot distinguish between the diffusion equation (9.10.7) or a wave equation.

9.10.2 A matter of curvature

Geometries which are both homogeneous and isotropic have constant (Gaussian) curvature.

Gaussian curvature is a measure of a surface's intrinsic geometry or the invariance of a surface to bending without stretching.

As we know, there are three distinct simply connected isotropic geometries in any dimension:

Euclidean with zero curvature, elliptic with positive curvature, and hyperbolic with negative curvature.

Pág. 06(15) - Affine Geometry

the study of those properties of geometric figures that remain unchanged by an Affine Transformation is called affine geometry.
For example,

since an affine transformation preserves straight lines and RATIOS of distances between POINTS, the notions of PARALLEL lines, MIDPOINTS of LINE segments, and tangency are valid concepts in affine geometry.
The notion of a CIRCLE,

however (poem), is not.
(A circle can be transformed into an ELLIPSE via an affine transformation. The equidistance of points on the circle from the circle center need not be preserved).
Affine geometry was first studied by Swiss mathematician Leonhard Euler (1707-1783)
Only postulates

1, 2, and 5 of EUCLID'S POSTULATES

remain valid in affine geometry.

Pag. 13(22) - Angle.

$$1 \text{ grau} = \frac{2\pi}{360} \cong 0.017 \text{ radian}$$

$$1 \text{ rad} = \frac{360}{2\pi} \cong 57.3^\circ.$$

The full surface area of the sphere is 4π steradian.

<u>Obs</u>: Trisecting an angle.

Pag. 512(521) - Trisecting an angle.

Pag. 372(381) - Pappu's theorems.

Pag. 249(258) - Heron's formula
Area of a triangle
solely in terms of the side-lengths of the triangle.

$$\boxed{\text{area} = \sqrt{s(s-a)(s-b)(s-c)}}$$

where
a, b, and c are the sides of the triangle,
and $s = \frac{1}{2}(a+b+c)$ is its "semiperimeter".

<u>Proved</u>: Heron's formula →

if θ is the angle between the sides of length a and b, then the area of the triangle is given by area

$$\boxed{\text{area} = \frac{1}{2} ab \sin(\theta).}$$

The <u>Law of Cosines</u> asserts that

$$\boxed{c^2 = a^2 + b^2 - 2ab\cos(\theta).}$$

Solving for $\sin(\theta)$ and $\cos(\theta)$, and substituting into the <u>standard identity</u> from Trigonometry,

$$\boxed{\cos^2(\theta) + \sin^2(\theta) = 1},$$

yields, after some algebraic work, Heron's result.

Heron claims that if x approximates the square root of a number N, then

$$\frac{x + \frac{N}{x}}{2}$$ is a better approximation.

For example: $3 \Rightarrow \dfrac{3 + \frac{10}{3}}{2} \cong 3.1667$

as an improved estimate.

Repeating the procedure yields

$$\frac{3.1667 + \frac{10}{3.1667}}{2} \cong 3.1623$$

as an even better approximation (In fact, $\sqrt{10} \cong 3.162277766$).

Then $(y - \sqrt{N}) = \frac{1}{2x}(x - \sqrt{N})^2$,

which shows that if the error $x - \sqrt{N}$ is small, then the error $y - \sqrt{N}$ will be even smaller. (We are assuming here that x is a value greater than 1.).

Aff: Newton's Method when applied to the function $f(x) = x^2 - N$.

Pág. 253 (262) – Hyperbola.

$$\sqrt{(x-c)^2 + y^2} = \left(\frac{c}{a}x - a\right)$$

valid for one branch of the figure at least.

Set $e = \frac{c}{a} = \frac{\sqrt{a^2+b^2}}{a} = \sqrt{1 + \frac{b^2}{a^2}}$.

This is called the <u>Eccentricity</u> of the hyperbola and has a value greater than 1.
The above equation can be rewritten:

$$\frac{\sqrt{(x-c)^2+y^2}}{x-\frac{a}{e}} = e.$$

See: hyperbolic functions

$$\cosh(t) = \frac{e^t + e^{-t}}{2}$$

$$\sinh(t) = \frac{e^t - e^{-t}}{2}$$

Pág. 255 (264) – hyperbolic geometry (Lobachevskian geometry)

Hyperbolic geometry is a Non-Euclidean geometry in which the famous <u>PARALLEL POSTULATE</u> fails in the following manner:
"Through a given point not on a given line, there is more than one line parallel to that given line".
Pág. 257 (266) – Identity ⇒ $3\arctan(1/4) + \arctan(1/20) + \arctan(1/1985) = \frac{\pi}{4}$ <u>20231107 180000</u> ~~SHH~~.

Pág. 116(118) - 6.6.3 Terceiro Período
Newton e a Mecânica Celeste
Pág. 119(121) -
Em novembro de 1684, Newton enviou a Halley um manuscrito de nove páginas intitulado:
"De motu corporum in gyrum"
(Sobre o movimento dos corpos em uma órbita) que, além de reafirmar a órbita elíptica dos planetas, continha uma demonstração matemática das três leis de Kepler.
Na carta exposição, Newton demonstrou que, se os planetas se movem numa órbita elíptica, eles precisam estar sob o controle do

Quadrado de uma força inversa direcionada para um foco da elipse e...

Obs: Ponto chave para a solução do problema.

... e demonstrou, ainda, que, sob a influência do quadrado de uma força inversa, a órbita dos planetas descreve uma seção cônica.

Análise:

O termo: "o controle do quadrado de uma força inversa direcionada para um foco da elipse."

Nós devemos ter mente que por causas das forças fundamentais da Física, a força fraca, a força forte, e o eletromagnetismo são responsáveis pela geração da "gravidade" que na realidade não existe, havendo apenas os efeitos sobre o espaço e a matéria.

Em relação à matéria, esta por sua vez nada mais é que uma forma de energia.

Einstein em sua fórmula demonstrou isso:

$$E = mc^2$$

O interessante é que Nikola Tesla disse que tudo é energia. Desta forma, a pseudo-gravidade é gerada pelas três forças fundamentais da Física.

Em relação ao termo: "a força de atração entre os corpos é inversamente proporcional ao quadrado da distância entre eles".

De forma bem simplista, esta descoberta foi feita com base na observação das estrelas por outros astrônomos, mas nós podemos

também deduzir de algo ainda mais simples decorrente do nosso cotidiano, por exemplo, um aluno sentado na última coluna de sala de aula e na última carteira, para ser ainda mais exagerado, na última coluna, na última fileira e na última carteira ou cadeira, bem no canto da sala, o que o aluno verá?

Ele verá que as carteiras mais próximas deles são maiores do que aquelas que estão no outro lado de sala de aula.

O tamanho das carteiras vai diminuindo a uma taxa fixa, ou seja, a carteira que está mais perto exerce uma força mais forte sobre o aluno do que aquela que está do outro lado. O mesmo acontece com os planetas e as estrelas. De um modo geral, a resposta está no tamanho da luz que se pode capturar, os carteiras mais próximas geram uma reflexão de luz maior por causa de sua proximidade enquanto as mais longínquas exercem uma menor reflexão de luz e portanto, uma pouca interferência por causa da distância.

Na Astronomia Moderna, a luz é uma fonte de dados, como tamanho da estrela, temperatura, distância do

observador etc. Portanto, a resposta já estava exposta a um aluno que entra pela primeira vez em uma sala de aula, mas por causa da tenra idade não tem o preparo para discernir o que já está lá exposto.

Pág. 120 (122) → No Universo, existem dois movimentos naturais: em repouso e em movimento uniforme (velocidade invariável) ao longo de uma linha reta.

Obs: O que é uma linha reta?
(straight line)

Nós devemos ter em mente que há várias acepções do que seja uma linha reta, não me refiro à questão moral, ética, comportamental, mas sim a linha reta real e a linha reta teórica.

Este assunto será devidamente aprofundado em uma oportunidade futura em um capítulo separado.

... ao longo de uma linha reta.
Existem três possibilidades de mudança:
a) uma partícula em repouso pode começar a se mover;
b) uma partícula em movimento retilíneo uniforme pode reduzir ou

acelerar sua velocidade;
3) ou uma partícula mudar de direção ao se desviar da linha reta.

Pág. 125 (127) - 6.7.1. Vácuo.

Pág. 320 (322) → Coulomb
apresentaria à Academia de Ciências três ~~Me~~ Memórias (1786, 1787 e 1788) consagradas à distribuição de
ELETRICIDADE
em condutores e à variação da densidade elétrica de dois condutores em contato.
Verificaria Coulomb que a carga elétrica se situa na superfície externa de um condutor, e que sua distribuição estática depende de sua
CURVATURA,
e que o ar não era um isolante ideal.[421]

RETORNANDO: FOCO DA ELIPSE

A elipse na mecânica celeste é causada por causa das forças fundamentais da Física. Caso houvesse a ação da gravidade como uma força fundamental independente e portanto atuante no mundo físico, a gravidade geraria em razão da sua própria

existência uma órbita circular perfeita e não elíptica.

Um outro aspecto a ser considerado, é a própria esfericidade do Sol que por si só não é perfeita, mas poderia ser, caso a "massa" do Sol fosse maior.

A esfericidade perfeita dependerá das três forças fundamentais da Física e não da gravidade, ou seja, não depende exclusivamente da ação da "pseudo-gravidade".

Importante:

$$\boxed{\text{CURVATURE} = \text{ENERGY}}$$

O Sol não é perfeitamente esférico por causa da energia representada pelas três forças fundamentais da Física, que curvam o espaço em volta da estrela e a própria estrela.

(A) ⟹ Com $\boxed{\text{M.U.S.}}$ haverá a uniformização do espaço de forma matemática, em que nós teremos a real compreensão da realidade do mundo físico representado de forma matemática. Assim, um Universo curvo expressado corretamente em uma superfície plana.

O erro da pseudo-gravidade gera o comportamento dos fenômenos da mecânica celeste como periélio e o afélio, ou melhor, a descrição foi feita de forma errônea e não corresponde com a realidade observada.

Vejamos: Pág. 105 (107).

Em 1609, ao estudar a órbita de Marte, descobriu Kepler o primeiro princípio do movimento planetário: Marte descreve órbita elíptica, de qual um dos focos é ocupado pelo Sol.

Verificando que no periélio (ponto de menor afastamento do Sol) a velocidade angular do planeta é máxima, decrescendo depois para chegar a um mínimo afélio (ponto da órbita em que a distância do Sol é máxima), pode KEPLER demonstrar serem iguais as áreas varridas, em tempos iguais, pelo raio do vetor que liga o centro do planeta ao do Sol; ou, em outras palavras, uma linha que une o planeta ao Sol descreve áreas iguais em períodos de tempo iguais, durante a revolução do planeta. Tal descoberta, que corresponde ao segundo princípio do movimento planetário, significa que quanto mais perto

do Sol mais rápida a velocidade do planeta.

b) 1021-História-da-Ciência-Vol.II-Tomo II...pdf

Pág. 144 (146) - Em meados de 1830, Faraday era famoso e respeitado, além de reconhecido como o maior cientista experimentador da Inglaterra de seu tempo.

Depois de ter inventado o dínamo, ter descoberto a indução eletromagnética e ter avançado nas pesquisas da eletrólise, mas sem formação matemática e com pouco conhecimento teórico, Faraday, para explicar a configuração formada por limalhas de ferro ao redor de um ímã (já observado por Pedro Peregrino no século XIII), sugeriria que as forças magnéticas atuariam como filamentos ou linhas de força que saíam de ímãs e circuitos.

A esse conjunto de linhas Faraday chamaria de "campo", em que as linhas de força magnética formariam o campo magnético, e as de força elétrica, o campo elétrico.

→

IMPORTANT:

A introdução de tal concepção (de ação de campo) seria extremamente útil, porquanto explicava que os corpos agiam sobre os outros corpos tanto por contato quanto pela interação dos campos por eles produzidos.

Como tais idéias contrariavam a noção de ação à distância de Newton, aceita universalmente, e temendo que viesse a ser vítima de violentos críticos, Faraday depositou no cofre da Sociedade Real, em 1832, documento com essas idéias; as instruções eram para ser o envelope aberto somente após a sua morte, o que não o impediu de, em janeiro de 1844, explicar, em conferência na Sociedade Real, as linhas principais de suas idéias sobre o assunto.

Essas idéias pioneiras seriam retomadas por MAXWELL.

1839 → GAUSS

"Teoremas gerais sobre as forças atrativas e de repulsão que atuam de acordo com o inverso do quadrado da distância"

→

Leis de Heinrich Friedrich Lenz (1804-1865) sobre a acção térmica da corrente eléctrica (1842/43), segundo as quais, uma corrente eléctrica induzida flui numa direcção tal que seja gerada uma oposição à mudança que a induziu
(se assim não fosse haveria uma violação da conservação de energia).

Pág. 71(73) – Para muitos autores, o marco inicial da Geometria diferencial será a publicação da "Disquisitiones circa superficies curvas" (1827), na qual GAUSS definiu a

CURVATURA

de superfície num ponto (curvatura gaussiana ou curvatura total)

e formulou seu famoso THEOREMA EGREGIUM, pelo qual a curvatura total K é uma propriedade absoluta da superfície.

Pág. 72(74) → Riemann abordaria aí as propriedades das variedades topológicas num número arbitrário de dimensões, e, influenciado pela teoria das superfícies, de Gauss, e por seus próprios trabalhos de Física ~~e~~ Matemática, definiria

o quadrado da distância de dois pontos infinitamente vizinhos dessa variedade por uma forma quadrática, e mostraria como medir curvatura dessa variedade.

obs: Quadrado da distância um padrão físico que se repete em toda a Física.

Trabalhos de Beltrami e Bianchi sobre as superfícies de curvatura constante

GABRIEL DARBOUX (1842-1917), sobre os sistemas triplos ortogonais (Leçons sur la théorie générale des surfaces, 1887/96, em 4 volumes).

Pág. 77(79) – Bernhard Riemann deduziu, da hipótese do ângulo obtuso uma Geometria não euclidiana.

→ foi influenciado pela teoria da curvatura das superfícies, de Gauss, em

"Pesquisas gerais sobre as superfícies curvas (1827)"

Na Geometria criada por Riemann, chamada por muitos como "riemanniana" ou "n-dimensional",

a soma dos ângulos maiores que dois retos é realizada sobre a superfície de uma esfera e nenhuma paralela pode ser traçada de um ponto fora de uma reta.

Pág. 78(80) – KLEIN denominaria a Geometria euclidiana (hipótese de ângulo reto) de "Geometria parabólica",

dado que suas retas cortam o core fundamentalmente num só

ponto, como a parábola no plano;

a de Lobachevsky - Bolyai - Gauss
(hipótese de ângulo agudo)
é chamada de
"Geometria hiperbólica"

por cortar, como a hipérbole, a reta ao infinito em dois pontos;

e a de Riemann
(hipótese de ângulo obtuso)
de
"Geometria elíptica",

por não ter suas retas, como a elipse, ponto de intersecção.

IMPORTANTÍSSIMO:

GEOMETRIA
HIPERELÍPTICA
MUSICHIANA

ou

GHM

→ revolucionária !!!

A Geometria
Hiperelíptica
Musichiana

ou

$\boxed{\text{GHM}}$

apresenta um diferencial arrojado e inovador, pois adequa os inconsistências da qualidade fática do mundo físico universal com o formalismo matemático.

Desta forma, com o uso da elipse dupla curvilínea projetada de forma ortogonal sobre uma superfície plana, nós obtemos

$\boxed{\text{M. U. S.}}$,

Mathematical
Uniforme
Space.

Geometria não-euclidiana ou Geometria Lobachevsky-Bolyai-Gauss → hipótese de ângulo agudo. (Geometria hiperbólica)

Geometria Riemanniana → hipótese de ângulo obtuso (Geometria elíptica)

Geometria Musichiana → hipótese de ângulo hiperelíptico projectivo (Geometria hiperelíptica)

GMH → Geometria Musichiana Hiperelíptica.

Em branco

(propositalmente)

Pág. 78(80) – Eugenio Beltrami (1835-1900), professor em Bolonha, Pisa, Pavia e Roma, mostrou que a superfície gerada pela revolução de uma tratriz em torno de uma assíntota é uma pseudo-esfera por ter uma (troca de caneta) uma curvatura negativa constante (a esfera tem curvatura positiva constante).

Se a reta entre dois pontos da pseudoesfera for definida como a geodésica por esses pontos, a geometria resultante terá as propriedades dos postulados de

$\boxed{\text{Lobachevsky}}$,

e com a curvatura total constante não nula será não euclidiana (conforme o teorema de Gauss).

Como o $\boxed{\text{plano}}$ é uma superfície com curvatura constant nula, concluiu Beltrami que a GEOMETRIA EUCLIDIANA

GEOMETRIA EUCLIDIANA

pode ser considerada como um intermediário entre as Geometrias de Lobachevsky e a de Riemann.

Pág. 108 (110) – Astrônomo Bessel fez a sua contribuição à Astrometria e do seu observatório em Königsberg, Bessel detectou, em 1838, com um heliômetro fabricado por Fraunhofer, que a estrela CISNE 61, descoberta por Giuseppe Piazzi, duas décadas antes, e admitida como a mais próxima da Terra, por sua rápida rotação se movia, em comparação com duas outras estrelas vizinhas, aparentemente num movimento anual elíptico; essa paralaxe só poderia ser causada pelo movimento de translação da Terra.

A paralaxe, calculada em 0,3136" (bastante próxima da atual de 0,30" ± 0,003"), corresponde a uma distância da Terra de 590 mil unidades astronômicas, ou de 10,4 anos-luz.

Pág. 137 (139) - O cientista alemão Helmholtz deu apoio à Teoria de Maxwell e incumbiu o jovem físico Heinrich Rudolf Hertz (1857-1894) de estudar o Electromagnetismo.

Hertz (entre 1885 e 1889) concluiu que as propriedades das ondas eram similares às da luz, o que o levou a concluir que as ondas de luz eram radiações eletromagnéticas, segundo as equações de Maxwell.

Estava dado o primeiro passo para o conhecimento do efeito fotoelétrico.

IMPORTANTÍSSIMO:

Pouco depois, o físico irlandês George Fitzgerald (1851-1901) sugeriu a hipótese, conhecida como da CONTRAÇÃO, pela qual o comprimento dos corpos materiais variaria, de acordo com seu movimento no éter, de uma quantidade que dependia do QUADRADO DA RAZÃO ENTRE →

QUADRADO DA RAZÃO ENTRE SUA VELOCIDADE e a VELOCIDADE DA LUZ.

Obs: Interessante!!!

Essa formulação seria aproveitada pelo físico holandês Hendrik Antoon Lorentz

Em novembro de 1892, informou à Academia de Ciências de Amsterdã ter adotado a hipótese de Fitzgerald sobre a contração do comprimento num trabalho que seria publicado em 1892/93.

Lorentz sustentaria que a massa de qualquer partícula aumentaria à medida que ela atingisse velocidades cada vez maiores, e que a contração da distância acarretaria uma dilatação do tempo.

Obs: Importantíssimo!!!

Einstein tirou deste argumento a sua Teoria da Relatividade.

Correcaria a surgir a noção da velocidade da luz como limite máximo no Universo[153].

Pág. 138(140) - 6.20.3 Eletrologia

A Eletrologia é a parte da Física que investiga os fenômenos elétricos e magnéticos e a interação entre seus respectivos campos. Seus amplos âmbitos foram unificados pelas famosas quatro Equações de Maxwell de 1873, formulação matemática das leis empíricas constitutivas do Eletromagnetismo.

Pág. 140 (142) - Em 1827, Ampère escreveria "Teoria matemática dos fenômenos eletrodinâmicos, deduzida unicamente da experiência", obra que coroaria suas investigações sobre a Eletricidade e o Magnetismo e na qual explicaria os fenômenos pela hipótese de uma interação newtoniana entre elementos de corrente.

Idealizou, então, a célebre "regra da mão direita" pela qual a deflexão da agulha Romane a direção dos dedos dobrados da mão direita quando esta segurasse o fio condutor, desde que mantivesse o polegar na direção da corrente elétrica.

Na obra, Ampère enunciou igualmente, quatro importantes princípios do Eletromagnetismo:

i) as ações de uma corrente ficam invertidas quando se inverte o sentido da corrente;

ii) há igualdade nas ações recebidas sobre um condutor móvel por dois outros, fixos, situados a igual distância do primeiro;

iii) a ação de um circuito fechado, ou de um conjunto de circuitos fechados sobre um elemento infinitésimo de uma corrente elétrica é perpendicular a esse elemento; e #

IV) **Obs.: Importante!!!**

Estudar com profundidade e atenção a perpendicularidade pois a curvatura do espaço age tanto na "massa" (energia) quanto na eletricidade e eletromagnetismo.

Analisar se há uma

CURVATURA ELÉTRICA E CURVATURA ELETROMAGNÉTICA

Interessante:

Plane Loci → we infer that the following were two of the loci considered:

(1) the locus of points the difference of the squares of whose distances from two fixed points is CONSTANT is a straight line perpendicular to the line joining the points;

(2) the locus of points the ratio of whose distances from two fixed points is constant (and not equal to one) is a circle.

The latter locus is, in fact, now know as the "Circle of Apollonius".

Pág. 136(158) - The Three-Line and Four-Line Locus

Apollonius → Book III:

The three- and four-line locus to which reference is made played an important role in mathematics from Euclid to Newton.

Given three lines (or four lines) in a plane, find the locus of a point P that moves so that the square of the distance from P to one of these is proportional to the

$\boxed{\text{product of the distances to the other two}}$

Obs: Estes cálculos serão alterados

... (or, in the case of four lines, the product of the distance to two of them is proportional to the product of the distances to the other two), the distances being measured at given angles with respect to the lines. Through modern analytic methods, including the normal form of the

$\boxed{\text{straight line}}$,

it is easy to show that the locus is a conic section — real or imaginary, reducible

or irreducible. If, for the three-lines locus, equations of the given lines are

$A_1x + B_1y + C_1 = 0$,

$A_2x + B_2y + C_2 = 0$, and

$A_3x + B_3y + C_3 = 0$, and if the angles at which the distances are those measured are θ_1, θ_2, and θ_3, then the locus of $P(x,y)$ is given by

$$\boxed{\frac{(A_1x + B_1y + C_1)^2}{(A_1^2 + B_1^2)\sin^2\theta_1} = \frac{K(A_2x + B_2y + C_2)}{\sqrt{A_2^2 + B_2^2}\sin\theta_2} \cdot \frac{(A_3x + B_3y + C_3)}{\sqrt{A_3^2 B_3^2}\sin\theta_3}.}$$

This equation is, in (general) general, of second degree in x and y; hence, the locus is a conic section.

"the theorem of Cavalieri":

If two solids have equal altitudes, and if sections made by planes parallel to the bases and at equal distances from them are always in a given ratio, then the volumes of the solids also are in this ratio (Smith 1959, pp. 605–609).

"History of Mathematics" and "Sourcebook in Mathematics" (1959)

Retornando: 20231109-Boyer-A history of Mathematics...pdf

Pág. 304 (326)

Cavalieri concentrated on an extremely useful geometric theorem equivalent to the modern statement in the calculus.

$$\int_0^a x^n \, dx = \frac{a^{n+1}}{n+1}.$$

IMPORTANT:

Fig. 15.2

The statement and the proof of the theorem are very different from those with which a modern reader is familiar, for Cavalieri compared powers of the lines in a parallelogram parallel to the base with the corresponding powers of lines in either of the two triangles into which a diagonal divides the parallelogram.

Let the parallelogram AFDC be divided into two triangles by the diagonal CF (Fig. 15.2) and let HE be an indivisible of triangle CDF that is parallel to the base CD. Then, on taking $\boxed{BC = FE}$ and drawing BM parallel to the base CD, ~~Then,~~ it is easy to show that the indivisible BM in triangle ACF will be equal to HE. Hence, one can pair all of the indivisibles of triangle CDF with equal indivisibles in triangle ACF, and, therefore, the two triangles are equal.

Inasmuch (Cangwanto) as the parallelogram is the sum of the indivisibles in the two triangles, it is clear that the sum of the first powers of the lines in one of the constituent triangles is

$$\boxed{\text{Half of the sum of the first powers of the lines in the parallelogram;}}$$

in other words:

$$\int_0^a x\,dx = \frac{a^2}{2}.$$

Through a similar but considerably more involved argument, Cavalieri showed that the sum of the squares of the lines in the triangle is one-third the sum of the squares of the lines in the parallelogram.

For the cubes of the lines, he found the ratio to be 1/4.

Pág. 314(336) - Classification of Curves.

Pág. 315(337) - Rectification of Curves.

Descartes added to the usual axioms of geometry one more axiom:

> Two or more lines (or curves) can be moved, one upon the other, determining by their intersection other curves.

Pág. 48 (61) - CONSTANT GRAVITATIONAL

$$G = 6.67259 \times 10^{11} m^3 Kg^{-1} s^{-2}$$

(3.5)

a) One day → 86400 s (SI)

b) mass of Sun → $m_\odot = 1.9891 \times 10^{30}$ Kg.

c) the mean distance between the center of mass Earth-Moon and the Sun, AU (Astronomical Unit), serves as length unit.

d) in these units the constant of gravitation is written as $\boxed{K^2}$, where K is referred to as the

$\boxed{\text{GAUSSIAN CONSTANT.}}$

Obs: Today, the AU is defined in such a way that the Gaussian constant K keeps the same numerical value, namely

$$\boxed{K = 0.01720209895 \sqrt{(AU)^3 m_\odot^{-1} d^{-2}}} \quad (3.6)$$

as it already had at Gauss's epoch.

IMPORTANT:

The constant K is also approximately the mean (média) daily motion of the center of mass of the Earth-Moon system in its orbit around the Sun, expressed in

rad/d, what corresponds to

$$\frac{180^\circ}{\pi \cdot K} \approx 0{,}986^\circ/d.$$

Cartesian coordinate system.

Coordinate system is defined by three orthogonal unit vectors

$$\boxed{e_i,\ i = 1, 2, 3},$$

originating from an origin O. For a right-hand system, we have

$$\boxed{e_3 = e_1 \times e_2},$$

where $e_1 \times e_2$ is the vector product of the two vector

$$\boxed{e_i,\ i = 1, 2}.$$

The set of the three unit vectors $e_i = 1, 2, 3$, is also called an orthonormal base in E^3.

A vector x pointing from the origin of the coordinate system to an arbitrary point in E^3 is called a position vector. Each position vector

may be represented as a linear combination of the three base vector:

$$x = x_1 e_1 + x_2 e_2 + x_3 e_3 \qquad (3.8)$$

Fig. 3.1
Trajectory of a point mass m in the inertial system.

Pag. 126 (143) – 6.5
/Harmonic Motion of a Classical Phase-Space Distribution

There is a particular intermediate initial width, which will turn out to be $\boxed{\sigma_{x0} = \sigma_0/\sqrt{2}}$, for which the classical phase-space distribution keeps its **shape while oscillating as a whole.**

This is the classical analog of the coherent state of quantum mechanics.

"The ~~sp~~ phase-space probability density corresponding to a **GAUSSIAN WAVE PACKET** without correlation between **momentum** and **position** at the initial time $\boxed{t=0}$ is

Pág. 127 (144) ⇒

$$p_i^{el}(x_i, p_i) = \frac{1}{2\pi \sigma_{x0} \sigma_{p0}} \exp\left\{-\frac{1}{2}\left[\frac{(x_i - x_{0i})^2}{\cancel{\sigma_{x_0}^2}\ \sigma_{x0}^2} + \frac{(p_i - p_{0i})^2}{\sigma_{p0}^2}\right]\right\}.$$

error!!!

Here x_{0i}, p_{0i} are the initial expectation value and σ_{x0}, σ_{p0} are the initial widths of position and momentum, respectively.

The covariance ellipse of the bivariate Gaussian is caracterized by the exponential being equal to $-1/2$.

Pág. 128 (145) – $\boxed{\text{Fig. 6.9}}$

Obs: Important!!!

We summarize our discussion by the following simple statements:

1) A classical phase-space distribution described by a bivariate Gaussian keeps its Gaussian shape.

2) Its center, which is the center of the covariance ellipse, moves on a circle around the center of the x, p plane with angular velocity ω.

3) The covariance ellipse keeps its shape but rotates around its center with the same angular velocity ω.

In figure 6.9 we illustrate the motion of the covariance ellipse for the three cases

$$\boxed{\sigma_{x_0} < \sigma_{p_0}, \quad \sigma_{x_0} > \sigma_{p_0}, \quad \sigma_{x_0} = \sigma_{p_0}.}$$

The Equivalence Principle

4.2.1. - Everything falls with the same acceleration.

"In contrast to eletric and magnetic fields the gravitational field exhibits a most remarkable property which is of fundamental importance for what follows. Bodies which are moving under the sole influence of a gravitational field receive an acceleration which does not in the least depend on the material or the physical state of the body"
Einstein.

Obs: Crítica:

Primeiramente, não há um contraste entre eletric and magnetic field, pois a "gravidade", ou seja, a pseudo-gravidade não existe, existindo apenas

os seus feitos decorrentes da eletricidade e magnetismo.

A atração dos corpos depende das três forças fundamentais da física, mas Einstein inverteu a ordem

PROPOSITALMENTE,

Vejamos:

a) a aceleração não depende do material ou do estado físico do corpo, isto é uma meia-verdade pois não é do material ou estado físico do corpo, mas sim da energia contida naquela "massa".

A massa nada mais é que uma forma de energia.

Portanto, depende da massa (sim) envolvida na questão.

b)

A massa que se refere Einstein decorre das forças fundamentais da física, pois ele descreveu os efeitos destas forças sobre os próprios corpos ou "massas", ou seja, desta forma, a própria energia é a força que atua no próprio corpo ou massa.

Os efeitos não são uma força

autônoma independente, mas o reflexo das próprias forças fundamentais da física.

Continuando a explicar:

Pág. 189 (206) → free-fall

"fifth force" ???

NO, let alone the fourth force.

Vejamos:

"More accurate measurements again confirmed the equality of free-fall accelerations in the gravitational field.

Obs: Neste caso, não há uma "gravitational field" e portanto, o free-fall não pode interferir no "gravitational field".

O mais grave de tudo o pseudo "free-fall" não existe como força independente e decorre unicamente das três forças fundamentais da física.

Aprofundando: (Pág. 189 (206))

Fig. 4.4 → The Dicke experiment.

The Earth is in free fall around the Sun. ← text

Obs: Não é verdade, as forças fundamentais de física continuam agindo sobre a Terra. A ausência da energia da própria Terra comportasse como uma "queda-livre". ← commentary

This should eliminate inertial forces in the Earth's frame.

Another way to see this is to say that centrifugal forces is exactly balanced by the gravitational attraction to the sun.

If different bodies have different free-fall accelerations in the same field this balance will not always occur.

In this experiment Dicke looked at a rotation of a torsion balance connected to one aluminium and one gold sphere on a 12 hour cycle as the Earth rotates.

The spheres have equal inertial masses.

Important: →

Broken line indicates rotation if gold falls with greater free-fall acceleration that aluminium.

Pág. 154 (178) - Chapter 4
The mean-value theorem:
Applications of the first and second derivatives.

The Mean-Value Theorem:

If f is differentiable on the open interval (a, b) and continuous on the closed interval [a, b], then there is at least one number c in (a, b) for wich

$$\boxed{f'(c) = \frac{f(b) - f(a)}{b - a}}$$

→ is to say that the graph of f has at least one point (c, f(x)) at which the tangent line is parallel to the line l.

IMPORTANT:

Utilizar este conceito como um instrumento de checagem de minha pesquisa. Paralelo e diagonal ao mesmo tempo.

Vejamos:

Figure 4.1.1

Análise:

A linha b (base) que contém a projeção dos pontos a, b e c sobre a abcissa x será utilizada como parte superior da curvatura espaço "tempo".

A função f (linha azul) como a curvatura do espaço elíptico da órbita de um planeta ou sistema solar.

A tangente t paralela a linha l será um referencial de checagem da projeção sobre a linha b (eixo x), mas devemos ficar atentos à linha l pois esta representa os dois pontos do nosso sistema de cálculo porque nós deveremos ter dois referenciais de estudo que deverão estar interligados entre si, que nós explanaremos a seguir:

a) Os pontos $(a, f(a))$ e $(b, f(b))$ deverão coincidir ou ser os pontos focais da elipse da órbita de um planeta ao redor de sua estrela ou do próprio sistema solar em questão.

Obs: Utilizar o sistema duplo elíptico curvo-musichiano,

esboçado anteriormente com os dois círculos, ponto Frégier e os pontos Me_1, Me_2, Me_3 - Musich points.

Obs: Esses pontos deverão ser alinhados entre si.

Vejamos:

1) P, M_1, S e Me_2.

2) Me_1, S, M_2 e Me_3.

Importante: Utilizar Pappus's theorem como checagem dos pontos colineares de modo a manter um referencial objetivo de uma linha reta (straight line).

Obs: Os pontos focais da elipse são essenciais da a estabilidade dos cálculos e sua respectiva projeção ortogonal sobre o plano.

b) Os pontos $(a, f(a))$ e $(b, f(b))$ deverão representar, em outra simulação, as bordas ou limites da órbita do sistema solar.

Os pontos $(a, f(a))$ e $(b, f(b))$ estão sobre a linha l e são dois pontos que estão na função f. (linha azul).

A tangent t deverá coincidir com a concavidade inferior da curvatura do espaço. (sistema duplo elíptico curvo murchiano).

Continuando o estudo sobre Mean-Value Theorem

First we will show that if a function f has a nonzero derivative at some point x_0, then for x close to x_0 $f(x)$ is greater than $f(x_0)$ on one side of x_0 and less than $f(x_0)$ on the other side of x_0.

Vejamos: Theorem 4.1.2.

Theorem 4.1.2.

Suppose that f is differentiable at x_0.

If $f'(x_0) > 0$, then

$$f(x_0 - h) < f(x_0) < f(x_0 + h)$$

for all positive h sufficiently small.

If $f'(x_0) < 0$, then

$$f(x_0 - h) > f(x_0) > f(x_0 + h)$$

for all positive h sufficiently small.

Proof:

- $f'(x_0) > 0$

by the definition of the derivative,

$$\lim_{K \to 0} \frac{f(x_0 + K) - f(x_0)}{K} = f'(x_0).$$

- With $f'(x_0) > 0$, we can use $f'(x_0)$ itself as ϵ and conclude that there exists $\delta > 0$ such that

$\Rightarrow$

if $0 < |k| < \delta$, then

$$\left| \frac{f(x_0 + k) - f(x_0)}{k} - f'(x_0) \right| < f'(x_0)$$

For such k, we have

$$-f'(x_0) < \frac{f(x_0 + k) - f(x_0)}{k} - f'(x_0) < f'(x_0)$$

and thus

$$0 < \frac{f(x_0 + k) - f(x_0)}{k} < 2f'(x_0).$$

In particular

$$(*) \quad \frac{f(x_0 + k) - f(x_0)}{k} > 0.$$

We have shown that $(*)$ holds for all numbers k which satisfy the condition $0 < |k| < \delta$.

If $0 < h < \delta$, then

$0 < |h| < \delta$ and

$0 < |-h| < \delta$.

Consequently,

$\rightarrow$

$$\frac{f(x_0+h)-f(x_0)}{h} > 0 \text{ and}$$

$$\frac{f(x_0-h)-f(x_0)}{-h} > 0.$$

The first inequality show that $f(x_0+h)-f(x_0) > 0$ and therefore $f(x_0) < f(x_0+h)$.

The second inequality shows that $f(x_0-h)-f(x_0) < 0$ and therefore $f(x_0-h < f(x_0)$.

IMPORTANT:

Next we prove a special case the mean-value theorem, know as

$\boxed{\text{ROLLE'S THEOREM}}$

(1691)

In Rolle's theorem, we make the additional assumption that $f(a)$ and $f(b)$ are both 0.

(See Figure 4.1.2) $\rightarrow$

Figure 4.1.2.

Obs: Utilizar esta configuração para criar um referencial de checagem sobre a curvatura do espaço (bending light).

In this case, the line through $(a, f(a))$ and $(b, f(b))$ is horizontal. (It is the x-axis).

The conclusion is that there is a point $(c, f(c))$ at which the tangent line is horizontal.

THEOREM 4.1.3
ROLLE THEOREM

Suppose that f is differentiable on the open interval (a, b) and continuous on the close interval $[a, b]$. If $f(a)$ and $f(b)$ are both 0, then there is at least one number c in (a, b) for which

$$\boxed{f'(c) = 0}$$

PROOF: If f is constantly 0 on $[a, b]$, then $f'(c) = 0$ for all c in (a, b).

If f is not constantly 0 on $[a, b]$, then f takes on either some positive values or some negative values.

Since f is continuous on $[a, b]$, f must take on a maximum value at some point c of $[a, b]$ (Theorem 2.6).

This maximum value, $f(c)$, must be positive. Since $f(a)$ and $f(b)$ are both 0, c cannot be a and it cannot be b. This means that c must lie in the open interval (a, b) and therefore $f'(c)$ exists. Now $f'(c)$ cannot be greater than 0 and it cannot be less than 0 because in either case f would have to take on values greater than $f(c)$. (This follows from Theorem 4.1.2.) We can conclude therefore that $f'(c) = 0$.

Livro: A Nova Física
Da Metafísica desinvertida.

Obs: A interpretação relativística de que a "energia é matéria radiante e matéria é energia condensada" expressa muito bem o materialismo absoluto trazido por Einstein e a ideia errônea de que a energia vem da matéria.

Tesla já havia realizado inúmeras

invenções de vulto, que corresponde à ausência total de matéria, ou seja, o vácuo é feito de energia.

A tecnologia de Tesla usava ressonâncias de ondas eletromagnéticas que ele denominava "ondas eletromagnéticas longitudinais".

Alguns ramos não ortodoxos da física denominam a energia do vácuo responsável pela tecnologia de Tesla de "energia escalar", um termo que se refere a uma forma de energia "não vetorial", ou seja, não originária da dimensão do espaço-tempo e portanto não definível por parâmetros temporais e espaciais, como são a energia potencial e a energia cinética.

Keppe: (conclui)

1) A matéria advém da energia e ambas não são equivalentes.

A energia (escalar de Tesla, ou essencial de Keppe) é hierarquicamente superior e sempre existe onde não há matéria (partículas), porém nem sempre há matéria onde pode haver onde há energia. A matéria simplesmente capta energia essencial e desprende energia secundária segundo a ressonância de sua estrutura interna.

Análise:

O nada gera a energia, portanto, o vácuo é a energia que cria os demais. Caso não houvesse o nada, nada teria sido criado. O nada cria o vácuo que é uma forma de energia "primordial" que permitirá a criação da matéria.

O nada existe por causa de Deus e existe antes do vácuo, o vácuo é consequência do nada. Aqui eu não estou falando nem de filosofia, teologia ou religião, mas apenas querendo demonstrar que o nada, criado por Deus, permitiu a criação de tudo, pois caso Deus não fizesse isto, ou seja, Ele ocupando tudo, não haveria espaço para a criação do nada e consequentemente do vácuo.

A afirmação de Keppe de que a energia sempre existe onde não há energia decorre para mim, do nada pois o vácuo já é uma manifestação da energia criadora do nada.

O vácuo decorre do nada e o nada é muito maior que o vácuo, pois para existir o vácuo há a

necessidade da existência do nada.

O Universo se expande sobre o nada, pois o nada já está lá onde o Universo, ou a borda dele, irá se expandir.

O fato de não existir nada na borda do Universo faz com que o Universo se expanda, criando-se assim, o vácuo. Conforme o Universo se expande o vácuo é criado sobre o nada e neste vácuo há energia free para o homem utilizá-la.

2) Existe apenas uma única substância, a Energia Essencial (termo keppeano para a energia escalar de Tesla), que é transcendente (não-material, não-temporal e não-espacial) e que produz a matéria através do fenômeno da ressonância.

Para Kepple, matéria é uma ressonância da Energia Essencial apresionada no tempo e no espaço.

Análise: O nada permite a criação do vácuo que contém energia, mas o nada

é muito maior do que a energia "aprisionada" no espaço-tempo.

Não há uma guerra energética mas sim uma deformação da própria criação do vácuo, pois conforme o Universo se expande sobre o nada, o vácuo é criado com a sua respectiva energia e posteriormente, a matéria é criada.

Por este motivo é que nós temos mais vácuo do que matéria, ou seja, o vácuo não preenche o espaço entre a matéria do Universo e sim a matéria que ocupa o vácuo previamente criado, e cria-se assim, os espaços entre as estrelas, planetas, galáxias etc.

3) Para Keppe, as energias sensíveis ao ser humano e detectáveis por instrumentos não são essenciais, correspondendo todas elas a subprodutos da energia primária (Energia Essencial). Isto implica que a tecnologia baseada na obtenção de movimento através da diferença de potenciais de energias secundárias (gravidade, eletromagnetismo etc) pode ser substituída pela tecnologia de

captação direta de energia primária (energia essencial) através do fenômeno da ressonância (da) de uma energia secundária, eletromagnética, por exemplo.

4) A energia essencial tem duas componentes, a cap e complementaçp, que correspondem aos dois sentidos que compõem a ressonância.

Keppe usa o conceito de "Potencial Puro", correspondendo à idéia de que a diferença de potenciais da fisica causa entropia acelerada do sistema pelo uso da energia apenas em um sentido. Quando o sistema está em ressonância, a entropia é minimizada e a eficiência maximizada, justamente porque o sistema passa a se beneficiar dos dois componentes complementares de aup e complementaçp.

O potencial puro pode ser visto como um vórtice causado pela ressonância do sistema e por onde passa a energia essencial.

Pág. 73 (80) → Leibniz →

Leibniz still saw the sphere as a surface embedded in three-dimensional Euclidean space. It happens, then, that a parallel in an embedded sphere is (itself) itself (if not a great circle), and Leibniz was able to think that the equidistant line to a circle is itself a circle, even on a spherical surface (a regular figure, in his terminology).

... Leibniz missed the most promising

example of a non-Euclidean geometry on the spherical surface, and did not properly grasp the full meaning of a geodesic.

Leibniz-on-the-Parallel-Postulate-and-the-Foundations-of-Geometry...pdf

Pág. 73(80) — [39] → rodapé

Since the above-mentioned marginal notes to Clavius' edition were probably written by Leibniz in 1679,

I should mention now that on Leibniz' copy of Clavius' Euclidis (p. 89), we find a handwritten remark to Clavius' proof about the straightness of the equidistant line, stating that when the Jesuit assumes that the line produced by the flow of the segment is not going up or down, he is already assuming what he would like to prove — straightness

("illud sursum vel deorsum supponit jam rectam").

Return: TEXT

Pág. 73(80) →

Leibniz' short discussion on the topic only restates that the straightness of the equidistant line should be proved

(what Clavius just assumes, Leibniz says) [39] and he puts forward (apbrsinta) an argument by symmetry.

Pag. 74 (81) -

Leibniz discusses the case of two lines AB and CD, that are intersected by a transversal AF as to form a right and an acute angle. The Parallel Postulate states

that, if extended far enough, the two lines will meet.

Leibniz imagines the rotation around A of the transversal AF toward (in direction a) the position of the inclined line AB, and considers that the point F will be under the line AC when (at some point of the rotation movement) the line AF reaches the position of AB.

Since F is below CD and A is above it by a continuity assumption, the extended AB (that is, the rotated AF) meets CD at some point proving the Postulate.

If the length AF is such that when AF reaches the position of AB the point F is already above the line CD (as in the case of A(F) in the diagram) nothing can be concluded. But then, we can take a point F on AF that is far enough from A to do the job.

The same will be true for any finite length of AF.

In the case in which AB and CD are parallel, however the same reasoning cannot apply, since the intersection would occur at infinity, and AF would be a

rotating unbounded line meeting the unbounded line CD at their extreme (which is impossible, since AF and CD have no ends).

Leibniz takes this as a further proof that lines cannot be moved (see text 3 above). Thus, Leibniz concludes, the present proof by rotation shows that AB and CD intersect, except in the case in which the intersection should occur at infinity; and this is the case in which AB and CD are

parallel,

or form equal angles with a transversal.

Even if we accept the whole reasoning on the immovability of an infinite line (and Leibniz himself observes that it would require more work), the last passage is unwarranted.

In hyperbolic geometry the transversal line AF, rotating, first intersects CD, than it becomes

asymptotic

with it, and finally it reaches the line AB (assuming, I mean, that AB is parallel to CD in the

hyperbolic plane, and thus the Parallel Postulate is false in this instance).

That is to say, Leibniz doesn't prove the central statement needed to establish the Parallel Postulate, that the intersection of the rotating AF with CD only occurs at infinity, when the angular sum with the transversal is two right angles.

Leibniz himself realized that this part of the proof was missing, and abandoned it. [43]

[43] → Leibniz' attempt was envisaged by a Medieval Hebrew mathematician (Moise Ha-Levi)

Obs: T. Lévy (1992) → Gersonide, le Pseudo-Tusi et le postulat des parallèles.

Pág. 73(80) – ... equidistant line to a circle is itself a circle ...

an example speaking in favor of the claim that the equidistant to a straight line is itself straight (no one mentioned the conic sections) [37]

[37] →

[37] → Clavius' Lemma 1 –
to his proof of the Parallel Postulate has a long discussion about the fact that the line equidistant to a circle is itself a circle.

Leibniz himself commented on Clavius' circle argument with a marginal note to his copy of Euclid, stating:

> "non semper lineae aequidistantes ejusdem sunt naturae; aequidistans parabolae parabola non est" (p. 90)

Interessante:
Leibniz – the great circles are the shortest and the most determined lines between two points on the sphere, and (moreover) they are uniform lines.[38]

[38] → In plano est recta, in sphaera est circulus maximus. (in De Risi 2007, p. 592)
→ Geometry and Monadology.

Pág. 74 (81)

As retas I, II e III são paralelas.

Vejamos:

a) $AG = AB$
b) $A(F) = A(H)$
c) $AF = AH$.

Obs: Não precisa o uso de compasso.

Através da Geometria Musichiana (Hiperelíptica ou Musdesic, baseado na hipótese de ângulo hiperelíptico projetivo, $AB \neq AF$ (não são paralelos) no plano euclidiano, são paralelos na G.M.H ou Musdesic.

Vejamos:

Leibniz comentando Clavius' Circle admite que uma linha equidistante nem sempre é equidistante.

A questão está na esfericidade, pois tecnicamente uma esfera apresenta uma simetria intrínseca que não permite que duas linhas não paralelas sejam paralelas.

O "pseudo-erro" "ab initio" por não serem paralelos contaminaria todas as simulações subsequentes.

A simetria intrínseca da esfera gera a propagação (das simulações) da não paralelismo nas simulações decorrentes.

Com a G.M.H ou Musdesic, a hipótese do ângulo hiperelíptico projectivo no qual a dupla elipse curva permite uma qual simulação da realidade demonstrando novas nuances de uma nova geometria permitindo que linhas não paralelas no plano euclidiano sejam paralelas, possibilitando a criação de novos paradigmas no mundo físico, criando novos Universos que seriam impossíveis com a

Matemática atual.

Musdesic é uma nova Matemática e consequentemente, uma nova geometria.

O ângulo hiperclíptico projetivo é um novo meio de representar a realidade, adequando o que existe ao formalismo atual matemático.

Aprofundando:

Return Pág. 74(81)

a) $AG = AB$

b) $A(F) = A(H)$

c) $AF = AH$

IMPORTANTE:

Neste exemplo, não há a necessidade da utilização do compasso para se obter o paralelismo entre as três retas.

O importante é o comprimento igual de cada segmento em ambas as retas.

AB não é paralelo ao segmento AF. (de reta).

simular com base na curvatura do espaço (bending light)

Important:

Fazendo um estudo mais aprofundado, nós podemos inferir mas sem provar ainda, que AB é paralelo a AF, pois caso haja a igualdade dos comprimentos dos segmentos de retas entre as duas retas AB e AF, gerando as três retas paralelas I, II e III nós podemos inferir que há um paralelismo intrínseco oculto entre essas duas retas.

Obs: A curvatura entre F e H, criada pelo compasso,

poderá representar em uma simulação a curvatura da luz (bending light) e a reta entre F1 e o plano projetivo no qual será projetado o sistema de dupla elipse curva.

Interessante:

Este paralelismo não se pode obter em uma esfera pois a simetria intrínseca interna ou externa impede que haja este paralelismo.

Como duas retas, que a princípio, não são paralelas no plano cartesiano geram três retas I, II e III paralelas.

A dupla elipse curva permite o paralelismo que será representado no plano no qual será projetado.

obs: Fazer as simulações e os cálculos.

Leibniz-on-the-Parallel-Postulate-and-the-Foundations-of-Geometry...pdf

Pag. 57(64) - Chapter 4 -
Leibniz' Attempts to Prove the Parallel Postulate.

Pag. 58(65) - Consider, for instance, that the main feature of a NON-EUCLIDEAN THEORY OF PARALLELISM (in hyperbolic geometry) is the existence of approaching straight lines that do not meet (asymptotic parallels); #

if one could disprove this possibility, the Parallel Postulate would be established;

but an asymptotic behavior of lines seems (parece) to depend on their curved and convex "shape" (as the usual Euclidean asymptotic lines are, obviously, not straight); a good definition of straightness (one might hope) would have dispelled (dissipado) the possibility of asymptotic straight lines, thus opening the way to a full-fledged (completo) demonstration of the Postulate.

Leibniz definitions are very numerous →

Definitions:

1) Straight line as the shortest line between two points.
(Borelli, Giordano, Fabri and Hobbes).

obj: Aristotle's statement (Phys. B 9, 200 a2-4) that from the essence of the straight line it follows that the

sum of the angles of a triangle is equal to two right-angles.

The notion of "straightness" seems not to be captured by "shortness", and the original intent of a definition of a straight line is that of expressing the clearly intuitive idea of a LACK OF CONVEXITY OR CONCAVITY (to use Clavius' words).

Leibniz explicitly mentions the fact that the property of shortness is never used in any proof of the Elements, and it is not useful to solve any foundational question.

Leibniz had a discussion with Giordano on this point, in which he appreciated that Giordano had been

able to employ the definition of a straight line as the shortest line to implement his proof of the Parallel Postulate: which, being concerned with the notion of equidistance, might rely (depender) as well on the idea of the shortest distance between two lines.

2) This was an improvement, in Leibniz's eyes, on Borelli's treatment of the Postulate.

Interessante:

In the end, however, Leibniz would have preferred that Giordano had employed in his foundational efforts a definition of a straight line that Leibniz showed he knew elsewhere: that of a rotational axis.[4]

Pag. 60(67) – Leibniz analysis situs.

The definition of the straight line as the locus of points which remain fixed in the motion of a body with two fixed points, i.e.

the axis of rotation,

is in fact the second and most important definition of a straight line that Leibniz use in his writings on analysis situs.

Its clearest mathematical characterization

is that the straight line is the only line between two points that is unique under isometries (that is, any other line connecting those two points has at least another isometric realization — imagine the reflection of that line in a plane). It is also connected with Leibniz' notion of UNIFORMITY, as the straight line so defined has the property that every segment of it is congruent to any other segment of the same length by a spatial isometry (its curvature being null).

Its importance for Leibniz is enormous, as it is by far his preferred definition ... including those aimed at proving the Parallel Postulate.

3) The third definition of a straight line that Leibniz uses is that of a self-similar curve.

Pág. 60(67) → each segment of a line is congruent with any other of equal length, this definition says that the straight line is the only line any segment of which is similar (in the proper geometrical sense) to any other segment (of any

length) of the same line.[9]

[9] → Any homothety of a factor λ applied to a curve transforms the curvature of it by a factor $1/\lambda$. If we want a similarity (that is, a homothety and a rigid motion) to bring a segment of a curve to coincide with the whole given curve (also bounded or closed), we have $\lambda > 1$, and thus the curvature lessening at every point.

The maximal curvature of the given curve, thus, may only be reached by the transformed segment if it is zero, that is, if the curve is a straight line.

Encyclopedia of Mathematics-Tanton.pdf
Pág. 170 (179) — Euclid's postulates

5. If two straight lines emanating from the endpoints of a given line segment have interior angles on one given side of the line segment summing to less than two right angles,

then the two lines, if extended, meet to from a triangle on that side of the line segment.

Obs: Pág. 171 (180) – In 1795, Scottish mathematician and physicist John Playfair (1748-1819) proposed an alternative formulation of the famous fifth postulate (today known as Playfair's Axiom).

This version of the axiom is considerably easier to handle, and its negation is easier to envision.

Nicolai Ivanovich Lobachevsky (1792-1856) e
János Bolyai (1802-1860), independently came to the same surprising conclusion:

the first four of Euclid's postulates together with the negation of Playfair's version of the fifth postulate will not lead to a contradiction.

Euclid: the parallel postulate cannot be proved a consequence of the remaining postulates of Euclid.

IMPORTANT:

Bolyai's system of

of hyperbolic geometry it is always the case that, for any point P in the plane, there are an infinite number of distinct lines through that point all PARALLEL to any given line not through P.

(In ordinary geometry, where the parallel postulate holds, there is only one, and only one, line through a given point P parallel to a given direction.

This is PLAYFAIR'S AXIOM.)

In his new geometry, angles in triangles sum to less than 180°, and the ratio of the circumference of a circle to its diameter is greater than π.

Obs: Na minha pesquisa, a razão da circunferência do círculo pelo seu diâmetro é menor que π.

Pág. 227 (236) – The German mathematician Bernhard Riemann (1826–66) discovered an alternative of non-Euclidean geometry in which Euclid's fifth postulate fails in a different way.

In a system of SPHERICAL GEOMETRY it is never possible to draw a line through a given point parallel to a given line.

Riemann in his famous 1854 lecture "Über die Hypothesen welche der Geometrie zu Grunde liegen" (On the hypotheses that lie at the foundation of Geometry), Riemann put foward (colocou para frente) the view that geometry can be the study of any kind of space of any number of dimensions, and later developed the mathematics needed to properly describe the shape of space.

Obs: Albert Einstein (1879–1955) later used this work to develop his theory of relativity.

ATENTION:

Cuidado!!! Atenção!!!

Nós devemos prestar atenção na seguinte diferença:

Bolyai → the ratio of the circumference of a circle to its diameter is greater than π.

Na página 255 (264):

In hyperbolic geometry all angles in triangles sum to less than 180°, and the ratio of the circumference of any circle to its diameter is less than π.

(Lobachevskian geometry).

Hyperbolic geometry (Lobachevskian geometry) is a non-Euclidean geometry in which the famous PARALLEL POSTULATE fails in the following manner:

Through a given point not on a given line, there is more than one line parallel to that given line.

→

Jules Henri Poincaré (1854-1912) later provided a simple model for this geometry and the means to easily visualize geometric results in this theory.

The "Poincaré disk" consists of all the points in the interior of the UNIT CIRCLE.

A "point" in geometry is any point inside this circle and a "line" is to be interpreted as a circular arc within the circle with endpoints perpendicular to the boundary of the circle.

Any diameter of the boundary circle is also considered a line.

Distances are not measured with a traditional ruler: points on the boundary circle are considered to be infinitely far from the center of the circle.

Bolyai and Lobachevsky showed that all but the FIFTH OF EUCLID'S POSTULATES hold in the hyperbolic geometry and, moreover, that this model of geometry is consistent (that is, free of CONTRADICTIONS).

This establishes that the parallel postulate cannot be logically deduced as a consequence of the

remaining axioms proposed by Euclid.

In hyperbolic geometry, all angles in triangles sum to less than 180°, and the ratio of the circumference of any circle to its diameter is less than π.

(Moreover, the value of this ratio is not the same for all circles). Also, it is possible for two perpendicular lines to be parallel to the same line.

Physicists, following the work of Albert Einstein, suggest that the geometry of our universe is hyperbolic: that it appears to us as Euclidean is a result of the fact that we occupy such a small portion of it. (This is analogous to the fact that it is difficult to recognize the Earth as around when living on it).

Pág. 355 (364) – non-Euclidean geometry.

non-Euclidean geometry:

1795 – John Playfair (1748-1819) presented an alternative, but equivalent, formulation of the parallel postulate:

through any point in the plane, there is precisely one line through that point parallel to any prescribed direction.

Recasting the postulate this way makes it apparent that negation of the famous fifth postulate has two parts. Either:

1. There are no lines through a given point parallel to a given direction.
2. There is more than one line through a given point parallel to a given direction.

From 1826 to 1829, Nicolai Ivanovich Lobachevsky (1792-1856) developed a consistent theory of geometry in which Euclid's fifth postulate fails in the manner described in point 2. → Hyperbolic Geometry.

In the 1850s, Georg Friedrich Bernhard Riemann (1826-1866) presented an alternative form of

geometry in which Euclid's fifth postulate fails in the manner describe in point 1 above.

In this theory, today called Riemannian geometry or Spherical Geometry, "lines" are great circles drawn on the surface of a sphere. Consequently, it is impossible to draw a pair of lines that never intersect.

Euclid's second postulate seems to state that straight lines should be of infinite length.

Riemann had the insight to note that "extended indefinitely" does not imply "infinitely long", thus allowing him to consider a geometry in which straight lines loop back on themselves.

In hyperbolic geometry all angles in a triangle sum to less than 180°, and the ratio of the circumference of a circle to its diameter is greater than π.

In spherical geometry, all angles in a triangle sum to more than 180°, and the ratio of the circumference of a circle to its diameter is less than π.

Euclidean Geometry, in which angles in a triangle always sum exactly to 180°, and the ratio of the circumference to diameter of any circle is precisely π (wrong!!!), M.U.S. can thus be regarded as an intermediate between the two.

Resume:

HG → Hyperbolic Geometry.

Parallel Postulate (Euclid's fifth postulate)

His fifth postulate states:

If two lines L and M subtended from a common line segment have interior angles summing to less than 180°, then those lines, if extended, will meet to form a TRIANGLE.

One can consequently conclude that if those angles sum to more than 180° then the lines, if extended on the other side of the given line segment, will form a triangle on that side.

(The sum of the supplementary interior angles will be less than 180°)

Furthermore, if the lines never meet, that is, if they are PARALLEL, then the sum of the two angles x and y shown cannot be less than nor greater than 180°, and so must equal 180°. We have:

For a pair of parallel lines with a TRANSVERSAL, as shown in the diagram below right, the angles labeled x and y must sum exactly to 180°. Consequently, the alternate interior angles of transversal are equal.

This is often taken as the statement of Euclid's fifth postulate. For this reason, it is (often) often called the parallel postulate.

As the parallel postulate is intimately connected with the formation of triangles, it is not surprising that one can use it to prove:

The sum of the interior angles of any triangle equal 180°.

1795 – "Elements of Geometry"
→ John Playfair offered a third, logically equivalent version of the parallel postulate:

Given a line L in the plane and a point P not on that line, then there exists one and only one line through P parallel to L.

This alternative version of the postulate is today called PLAYFAIR'S AXIOM.

1829 → Nikolai Ivanovich Lobachevsky (1792–1856)
→ discover a consistent theory

of a Non-Euclidean Geometry.

We now have three assertions:

1. Euclid's parallel postulate;
2. Angles in a triangle sum to 180°.
3. Playfair's axiom.

These three statements are logically equivalent, that is, any one implies the other two. To see this, it suffices to show that (3) implies (2), (2) implies (1), and that (1) implies (3).

We will need to make use of the converse of Euclid's parallel postulate:

If a transversal across a pair of lines yields equal alternate interior angles, then the lines are parallel.

As the EXTERIOR-ANGLE THEOREM, this statement can be proved without making use of any of the three statements above.

Consider now the three implications:
(3) implies (2):

Given a triangle with angles

a, b, and c as shown in the diagram on page 378,

Equivalent versions of the parallel postulate.

... 378, draw two lines at the apex that copy angles a and b. Given that both yield equal alternate interior angles across a transversal, both lines are parallel to the base of the triangle.

By Playfair's axiom there is only one such ~~line~~ (line). Thus angles a, b, and c all lie on the same straight line and so sum to 180°.

(2) implies (1):

In the middle diagram on page 378, suppose that lines L and M are parallel, and so never meet. Could it be that angles x and y sum to less that 180°? Draw a point P on line M, and slide it along M sufficiently far so that the angle of the triangle APB at P is

less than $180 - x - y$.

Clearly the angle in this triangle at A is less than x.

We now have a triangle with three angles that sum to something less than $x - (180 - x - y) + y = 180°$.

This is impossible by our assumption that (2) is true. It cannot be the case that L and M are parallel after all.

(1) implies (3):

Discussion on the exterior-angle theorem shows that there certainly exists at least one line through a point P parallel to a given line L.

Suppose there are two such lines. Call them (them) M and M' as shown in the diagram above.

Draw any line from P to L.

Since, by (1), we are assuming that alternate interior angles are equal for parallel lines, both angles a and b shown are equal to x.

Consequently, M and M' must be the same line.

Pág. 473 (482) → Spherical Geometry

Spherical Geometry
(elliptic geometry, Riemannian geometry)

Discovered in 1856 by Georg Friedrich Bernhard Riemann (1826-66), and later slightly modified modified by Felix Klein (1849-1925), spherical geometry is a non-euclidean geometry in which the famous

PARALLEL POSTULATE

fails in the following manner:

Through a given point not on a given line, there are no lines parallel to that given line.

Riemann used the surface of a SPHERE as a model of this geometry by interpreting the word line to mean a great circle on the sphere. Given that in a theory of geometry two lines are meant to intersect at just one point (yet any two great circles intersect at two ANTIPODAL POINTS), it is appropriate then to interpret the word point

in spherical geometry as an antipodal pair of points on the surface. In this setting, it is now also true that

$\boxed{\text{any two distinct points determine a unique line.}}$

Riemann and Klein proved that all but the fifth of EUCLID'S POSTULATES hold in this model and, moreover, that this model is consistent (that is, free of CONTRADICTIONS).

This establishes that the parallel postulate cannot be logically deduced as a consequence of the remaining axioms proposed by Euclid.

In spherical geometry all angles in triangles sum to more than 180°, and the ratio of the circumference of any circle to its diameter is $\boxed{\text{greater than } \pi}$ (and this value varies from circle to circle).

Obs: Cuidado!!! ... greater than π.

$\Delta > 180°$ and $\frac{C}{D} > \pi$ (?)

(atenção!!!)

IMPORTANT:

Pág. 46(55) – Bolyai, János (1802-1860) is remembered for his 1823 discovery of Non-Euclidean geometry.

...

In Bolyai's system of HYPERBOLIC GEOMETRY it is always the case that, for any point P in the plane, there are an infinite number of distinct lines through that point all PARALLEL to any given line not through P.

(In ordinary geometry where the parallel postulate holds, there is only one, and only one, line through a given point P parallel to a given direction. This is PLAYFAIR'S AXIOM)

In his new geometry, angles in triangles sum to less than 180° and the ratio of the circumference of a circle its diameter is greater than π.

Pág. 170 – Chapter XIV
Areas and Volumes

The subjects area and volume offer some of the most striking points of disparity between euclidean and non-euclidean geometry.

Pág. 174 – In Chapter III we defined as the discrepancy of a triangle, the absolute value of the difference between the sum of the measures of the angles and π. Let us now define as the excess of our triangle the expression

$$\boxed{e = A + B + C - \pi}.$$

This will have the same sign as $\frac{1}{K^2}$, the measure of curvature of space.

We have

$$\sin\frac{e}{2} = -\cos\sigma = \frac{\sin(ABC)}{4\cos\frac{1}{2}\frac{a}{K}\cos\frac{1}{2}\frac{b}{K}\cos\frac{1}{2}\frac{c}{K}}$$

(14)

$= 4$

$$\lim e = \frac{1}{2} \lim (ABC)$$
$$= \frac{1}{2K^2} \lim bc \sin A$$
$$= \frac{1}{2K^2} \lim a\, \overline{AA'}.$$

Pág. 178 – Theorem 5.

The area of a convex polygon is the quotient of the excess of the sum of its angles over $(n-2)\pi$ divided by the measure of curvature of space.

Let the reader show that the area of a proper circle is

$$2\pi K^2 \left(1 - \cos \frac{r}{K}\right) \quad (17)$$

the total areas of the elliptic and the spherical planes will be

$$2\pi K^2, \; 4\pi K^2.$$

In the hyperbolic plane regions may be found having any desired area.

Pág. 175 ⇒ Theorem 3

The area of a region of a plane is the sum of the areas of any two regions into which it may be divided provided that these two have no common area.

Pág. 177 - $Area = k^2(A + B + C - \pi)$ (16)

Pág. 02(13) - Chapter 1
Euclidean Geometry and Non-Euclidean Geometry

Pág. 03(15) - Fig. 1.1.
On the axiom of parallelism of straight lines.

Pág. 02(14) - 1.1. Euclidean Geometry
The basis of Euclid's geometry is five postulates (axioms that do not require proof):

5. If a straight line meets two other straight lines in such a way that on one-sided they form two internal one-sided corners, in total less than two right angles, then these straight lines, if continued

indefinitely, will intersect on the side from which the one-sided corners are less than two right angles.

From the fifth postulate it follows that if there are two parallel lines, i.e., the straight line intersecting them forms two inner one-sided angles to the sum of two straight lines, then these parallel straight lines will not intersect no matter how much they continue.

Euclidean geometry, according to which space is infinite, homogeneous, isotropic and three-dimensional, became the basis of classical physics.

However, the fifth postulate of parallel straight lines has been in doubt since the 19th century. It is easy to make such a construction (Figure 1.1). We will draw two parallel lines, and also in the plane of these lines we will draw a circle C of an arbitrary radius centered at point A between these lines so that the circle does not intersect straight lines.

→

Figure 1.1 On the axiom of parallelism of straight lines.

We will successively decrease the angles of inclination of the rays to zero in both sets of rays. In this case, the points α_n and B_n will move along straight lines L_1 and L_2 right to infinity.

The images of these points A_n and B_n on the circle C will approach each other as closely as you like. At a zero angle of inclination of the rays the point A_n will coincide with the point B_n. Since there is a one-to-one correspondence between the points α_n and A_n, as well as between the points B_n and B_n, the alignment of the points A_n and

B_n will mean the alignment of the points α_n and B_n, that is parallel lines L_1 and L_2 intersect at infinity.

∴ The inconclusiveness of the postulate of parallel lines led to the construction of geometries as a whole on the basis of concepts and axioms that relate only to the immediate vicinity of each point. So, the possibility arose of creating geometries based on differential geometry (Hilbert, Cohn-Vossen, 1932).

Pág. 04(16) 1.2.
Non-Euclidean Hyperbolic Geometry.
In non-Euclidean geometry postulate 5 of the Euclidean system of postulates is replaced by the axiom:

Through a point that does not lie on a given straight line there are at least two straight lines that lie with this straight line in one plane and do not intersect it. This is Lobachevsky's axiom (Lobachevsky, 1829, 1835).

According to this axiom, on the plane through the point P, which lies outside the straight-line A'A, more than one straight line (Figure 1.2) does not intersect the straight-line A'A.

Figure 1.2. – Lines passing through a point in non-Euclidean geometry.

Non-intersecting straight lines fill the part of the beam with apex P lying inside the vertical angles TPU and U'PT' located symmetrically relative to the perpendicular PQ.

The straight lines forming the sides of the vertical corners separate the intersecting straight lines from

the non-intersecting straight lines and are themselves intersecting straight lines. These boundary lines are called parallel at point P to line A'A, respectively, in its two directions: T'T parallel to A'A in the direction of A'A and U'U parallel to A'A in the direction of A'A. The rest of the non-intersecting lines are called lines diverging from A'A.

The angle α $(0 < \alpha < \pi/2)$, that the parallel to the point P forms with the perpendicular PQ,

$$\boxed{\angle QPT = \angle QPU' = \alpha}$$

is called the angle of parallelism of the segment $PQ = a$ and is denote by $\alpha = \Pi(a)$. When $a = 0$ the angle $\alpha = \pi/2$; with increasing a angle α decreases so that for each given α there is a certain value of a. This dependence is called the Lobachevsky function

$$\Pi(a) = 2 \operatorname{arctg}\left(e^{-a/k}\right), \quad (1.1)$$

where k is some constant that determines a segment fixed in magnitude. It is called the radius of curvature

of the Lobachevsky space.

There is an infinite number of Lobachevsky spaces, differing in the size of K.

The model of the Lobachevsky plane can be a surface with constant negative curvature.

The simplest example of such a surface would be the pseudosphere (Figure 1.3) (Beltrami, 1868).

Figure 1.3. Pseudosphere.

There are also other models of Lobachevsky geometry (Klein, 1928).

Pág. 05 (17) — 1.3

Non-Euclidean Eleptical Geometry.

The fact that the sphere is the

spatial form of elliptic geometry is seen directly, since the curvature of a sphere of radius R in all such cases is equal to $1/R^2$, that is, it is positive and constant.

It can be shown that a metric of constant curvature $K > 0$ can also be introduced on the projective plane. Consider some plane α of Euclidean space and some sphere C. Let the plane of Euclidean space be located horizontally, and the sphere is above the plane.

Let O be the center of the sphere. Obviously, each point of the sphere, if it does not lie on the equator, is projected from the center O' to a certain point of the plane α. Diametrically opposite points of the sphere are projected at the same point. The points lying on the equator have no projections. Supplement the plane α with infinitely distant points and introduce a system of neighborhoods into the set of all points of the extended plane. Then we get a projective plane, which we will denote by $\bar{\alpha}$.

Let us agree to say that the horizontal line a passing through the point O intersects the projective plane $\bar{\alpha}$ at an infinitely distant point lying

on any of the straight lines in the Euclidean plane α parallel to the line a. Under this condition, each point of the sphere is projected from the center O to a certain point of the projective plane $\bar{\alpha}$, and each point on $\bar{\alpha}$ is the projection of two diametrically opposite points of the sphere.

Let us now introduce geographic coordinates on sphere Θ. On the projective plane, the coordinates of some point M will be considered numbers equal to the geographical coordinates of that point of the sphere, which has its projection point M. Since each point of the projective plane is the projection of two opposite points of the sphere, then each point of the projective plane, along with coordinates, also has coordinates. Now, in each neighborhood of a point on the projective plane, we introduce the metric form

$$dS^2 = R^2(\cos^2\psi\, d\varphi^2 + d\psi). \quad (1.2)$$

In this case, the matrix shape of the sphere is written in the form (Efimov, 1945).

$$dS^2 = \cos^2(K^{1/2} v)\, d^2 u + d^2 v \quad (1.3)$$

→

To reduce expression (1.2) to expression (1.3), it is sufficient to set

$$\varphi = K^{1/2} u, \quad \psi^{1/2} v$$

and take into account the relationship between the curvature and the radius of the sphere

$$K = 1/R^2.$$

The geometric system of the metrized projective plane $\bar{\alpha}$ is called Riemannian non-Euclidean geometry.

In the (the) geometric system of the metrized projective plane $\bar{\alpha}$ (elliptic plane), any two points define one and only one geodesic line passing through them.

Every two lines have a common point. An elliptical plane has no parallel lines. In an elliptical plane (Riemann geometry), every line intersects another.

The well-known objects of two-dimensional differential geometry can be generalized into multidimensional geometry (Efimov, 1945; Cartan, 2009).

Cont.) ...
Riemann introduced the concept of an n-extended quantity and defined a measure definition that is possible on an n-dimensional manifold

$$dS^2 = \sum g_{ik}\, dx_i\, dx_k,$$ where

the coefficients in front of the product of the differentials of the variables are functions of coordinates.

Pág. 07(19) - 1.4.

Non-Euclidean Geometry of the Higher Dimension Polytopes!

Riemann pointed out the contours of geometric figures as one of the examples of the n-extended value.

The space of these figures, therefore, has dimension n and is limited, i.e., certainly.

The condition for space to be finite is one of the basic conditions in Riemann geometry.

However, the curvature of space will be zero if the planar (two-dimensional) elements of the figure have zero curvature. Thus, there is no need to use the apparatus of differential geometry. Due to the finiteness of the higher-dimensional polytope and the presence of the polytope contour (i.e., the boundary), the higher-dimensional polytope space is closed. Therefore, the system of axioms of n-dimensional Euclidean space, extended from the system of axioms of three-dimensional Euclidean space, cannot be applied to the polytope space of higher dimension. In particular, line segments located inside the higher-dimensional polytope cannot be

extended outside the higher-dimensional polytope. The space of a polytope of the highest dimension has a special structure that determines the conditions for the belonging of elements of different dimensions to each other, as will be shown in the next chapter. Therefore, the conditions for membership of elements of different dimensions, adopted in the system of axioms of n-dimensional Euclidean geometry, are not fulfilled in the polytope of the highest dimension.

In this regard, it should be recognized that the geometry of the space of polytopes of the highest dimension is not Euclidean.

Conclusion:

This non-Euclidean geometry is not related to the curvature of space and therefore cannot be attributed to either hyperbolic or elliptical non-Euclidean geometries.

Subject to the accepted values
a and d can get

$$R = \frac{0.81}{\pi-\gamma}\ nm.$$

For example, in case $\gamma = 140°$
is $R = 1.6$ nm.

Obs. This radius value is close
to the experimental helix radius
of nucleic acid measured by
Watson and Crick.

b) 20231122 - Sochi - General Relativity Simplified - (2020).pdf

Pag. 22 (23) -

A space (~~sph~~) is flat if it is possible to find a coordinate system for the space with a diagonal metric tensor whose all diagonal elements are ± 1; otherwise the space is curved.

More formally, an nD space is flat if it is possible to find a coordinate system in which the quadratic form $(ds)^2$ is given by:

$$(ds)^2 = \sum_{i=1}^{n} \xi_i (dx^i)^2 \qquad (2).$$

where the indexed ξ are ± 1 while the indexed x are the coordinates of the space.

Geodesic curve is the most "straight" or most "direct" route connecting two points in a given space.

Geodesic curves are normally, but not necessarily, the curves of shortest length.

Interessante : NULL GEODESIC.

Null geodesic is the geodesic path that is followed by a light signal (or any massless object to be more general) in the spacetime (assuming the signal is not under non-gravitational influence). The line element $d\sigma$ (and hence the spacetime interval σ) vanishes identically along null geodesic and that is why it is "null".

Pág. 290 (291) – Figure 7.
A simple graphical illustration of the precession of perihelion PP where P_1, P_2, P_3 represent successive perihelia. We note that the indicated precession can have various causes (and hence we use PP instead of $\delta\phi$).

8.2 Light Bending by Gravity.

Light bending (or light deflection) by the gravitational field of a gravitating body, like the Sun, is one of the major predictions of general relativity because according to this theory the bending of spacetime by matter and energy should result in bending the geodesic paths of the spacetime and hence

the physical objects, whether(se) massive like material particles or massless like photons, which follow these geodesic paths in their free fall (i.e. in the absence of forces other than gravity) should move along curved trajectories.

Analisar.

The bending of light in gravitational fields may also be justified qualitatively by the equivalence principle since light bends in accelerating frames and hence it should also bend in gravitational frames. (frames).

In fact, light bending by gravity can be derived even (mermo) from the Newtonian theory and hence it is not an effect that is specific to general relativity.

However, the Newtonian prediction is quantitatively different from the prediction of general relativity.[368]

[368] ⇒ commonly recognized Newton prediction which is based on derivation. However, some theories based on the Newtonian gravity seem

to have different predictions;

Figure 8

A simple sketch depicting the bending of a light ray from a star as it passes by the Sun toward (in direction of) the Earth and hence it is deflected by the gravity of the Sun.

Using the geodesic equations of null geodesic in the Schwarzschild metric, it can be shown that the deflection of light by the gravity of a static and spherically symmetric gravitating body is a given

$$\delta\phi = \frac{4GM}{c^2 d} \qquad (323)$$

where $\delta\phi$ is the angle of deflection in radians,
G is the gravitational constant,
M is the mass of the gravitating body,
c is the characteristic speed of light and

d is the distance of closest approach of light to the center of the gravitating body.

Pág. 291(292) - Problems

1. The problem of light bending is a problem of motion along geodesic trajectories in spacetime because the light is in free fall (?) under the influence of gravity alone.

Therefore, this problem should be investigated as a geodesic problem in the Schwarzschild metric and hence we can use the results that we obtained in § 4.1.2.

Obs: § 4.1.2. Pág 215(216) →

Geodesic Equation in Schwarzschild Metric.

→ using the Christoffel symbols (§ 4.1.1).

Off: Pág. 212 (213) - Schwarzschild radius?

Schwarzschild radius (which may also be called gravitational radius and is usually associated with black holes although (embora) it is not specific to them) is the distance from the center of the gravitating object to the points of space where the escape speed is equal

to the characteristic speed of light c (assuming that the mass of the object is confined to the region within the Schwarzschild radius).

We should note that this definition is essentially classical. In fact, the general relativistic definition of the Schwarzschild radius is obtained from the Schwarzschild metric and the singularity at $r = \frac{2GM}{c^2}$ (or by comparing the classical and general relativistic formulations in the classical limit, as will be discussed in § 5.1). Anyway, the classical and relativistic definitions are equivalent although the interpretation of r may differ (see § 6.2).

The Linearized Field Equation

We investigate the linearized form of the Field Equation which is used as a good approximation to the full (non-linear) Field Equation in the case of weak gravitational fields where the spacetime is pseudo- or quasi-Minkowskian and hence it deviates slightly form the flat geometry of the authentic Minkowskian spacetime.[241]

[241] → In fact, gravity in the weak field regime can be seen as a minor curvature in spacetime and as a Lorentzian field in a flat Minkowskian spacetime. From the latter perspective, it is like electromagnetism in special relativity.

Important:

A linearização desta equação não é desejável em virtude da própria realidade das forças fundamentais da física que regem o Universo e a utilização "flat Minkowskian spacetime" gera erros que se propagam em todos os cálculos matemáticos envolvidos no perfeito entendimento

dos mecanismos que regem o sistema em questão.

11. What is the significance of the fact the divergence of the energy-momentum tensor is zero?

Also link this to the vanishing of the divergence of the Einstein tensor!

Answer:
Let first see what is the significance of the divergence of a rank-1 tensor (i.e. vector) field in 3D space. The divergence of a vector field is a

measure for the spatial rate at which a certain quantity (e.g. mass) "diverges" or "converges" in the space.

So if we have a source or sink for that quantity in the concerned region of space then the divergence is non-vanishing because the quantity diverges or converges due to the positive or negative supply by the source or sink. Otherwise the divergence should vanish because there is no supply. So at the root of the divergence (or rather divergence-free) is the concept of conservation or the denial of creation and annihilation since each diverging quantity from a certain location in space should come from a source and each converging quantity to a certain location in space should go to some sink.

On generalizing this idea and applying it to energy-momentum tensor in 4D spacetime, we can see that the vanishing of the divergence of the energy-momentum tensor originates from the conservation of energy and momentum, as we concluded in a rather different way earlier.

Pág. 165(166) – the link of this to the vanishing of the divergence of the Einstein tensor should be obvious because the divergence-free nature of the Einstein tensor (see §. 2.13)

off: IMPORTANT:

Pág. 72(73) – 2.1 Space, Coordinate System and Transformation

A space is descri as Euclidean when it can be coordinated by a Cartesian coordinate system[100] and

[100] – this is equivalent to the condition that there is a permissible coordinate transformation that takes the general quadratic form

$$(ds)^2 = g_{ij}\, dx^i\, dx^j$$

of the space to the Cartesian quadratic form

$$(ds)^2 = \sum_{i=1}^{n} (dx^i)^2.$$

see (?)

In other words, there is a permissible coordinate transformation that takes the metric tensor g_{ij} to the Kronecker delta tensor δ_{ij}.

Return: Pág. 72(73)

[100] ... and described as flat when it can be coordinated by a Cartesian or quasi-Cartesian system.

If the space cannot be coordinated by a Cartesian or quasi-Cartesian system it is described as curved.

A Riemannian space is a space characterized by having a symmetric rank-2 tensor called the metric tensor that represents the geometry of the space.

Riemannian space may also may also be characterized (and hence restricted) by the condition that it is possible to construct a locally Cartesian coordinate system at any of its points, i.e. it is locally Euclidean or flat! [101]

[101] ⇒ We note that there are some abstract metric spaces which are not Euclidean or flat

even locally and accordingly they are not Riemannian.

Riemannian space may similarly be characterized by having a line element ds whose square is defined by the quadratic form

$$(ds)^2 = g_{ij}\, dx^i dx^j$$ where

g_{ij} is the metric tensor,

dx^i and dx^j are coordinate differentials and

i and j range over the space dimensions. [102]

[102] ⇒ To be more clear, $(ds)^2$ is the square of the line element ds while $g_{ij}\, dx^i dx^j$ is the quadratic from (since it is quadratic in dx) although (embora) it is common to call $(ds)^2$ the quadratic form (referring to its mathematical expression $g_{ij}\, dx^i dx^j$).

Conventionally, the quadratic form (which is based on the metric tensor) of Riemannian space is

positive definite. Hence, a space whose characteristics are similar to the characteristics of Riemannian space but its quadratic form is not positive definite (i.e. it is Riemannian apart (from) from this mathematical nicety) is commonly known as pseudo- or quasi-Riemannian.

As indicated earlier physicists generally do not discriminate between Riemannian and pseudo-Riemannian and hence both might be described as Riemannian.

Return: Pág. 165(166) →

see (§ 2.13) →

the divergence-free nature of the Einstein tensor (see § 2.13) means that the curvature of spacetime is "conserved" in some sense and hence it can only be generated from a source of "energy-momentum".

In fact, this link between the curvature of spacetime (as represented by the Einstein tensor) and the energy-momentum (as represented by the energy-momentum tensor) is embedded

in the Field Equation which correlates the Einstein tensor to the energy-momentum tensor (and hence it correlates the divergence-free nature of the curvature to the divergence-free nature of the energy-momentum, as we will see in § 3). [221]

[221] → In fact, this is the essence of the general relativistic paradigm that the energy-momentum is the physical source of the geometric curvature which represents the gravity.

Pág. 165 (166) – 12.

Make a comparison between the Einstein tensor G and the energy-momentum tensor T.

→ We note the following:

a) Both G and T are rank-2 symmetric tensors in 4D spacetime and hence each has 16 components 10 of which are independent;

b) the divergence of both tensors is zero;

c) G and T are proportional to each other according to the Field Equation (see § 3.2);

d) G is geometric while T is physical and

e) the physical dimensions of G are reciprocal area while the physical dimensions of T are energy density.

Return : Pág. 292(293)

In fact, all we need from that system is Eq. 182 because the essence of light bending is represented by a correlation between

$r = 1/u$ and ϕ (i.e. how ϕ changes r changes)

and that is what Eq. 182 is about. So, our investigation here starts from Eq. 182, that is:

$$\frac{d^2 u}{d\phi^2} + u = \frac{3GMu^2}{c^2} \qquad (324)$$

In brief, what we need for finding a formula for light bending by gravity is to solve Eq. 324 and hence infer the angular deflection in the path of light that is caused by the gravitational field of the star. Now if we consider a light ray grazing a typical star that represents a gravitating object then we have

$u \gg \frac{3GMu^2}{c^2}$. This can be

verified by taking the ratio of $\frac{3GMu^2}{c^2}$ to u and using the Sun to represent the typical star, that is:

$$\frac{3GMu^2}{c^2 u} = \frac{3GMu}{c^2} = \frac{3GM}{c^2 r} \simeq$$

$$\frac{3 \times 6.674 \times 10^{-11} \times 1.989 \times 10^{30}}{(3 \times 10^8)^2 \times 6.9551 \times 10^8} \simeq$$

$$6.362 \times 10^{-6}$$

where r represents the radius of the Sun since the ray is grazing (in fact r should be radial coordinate).

Therefore, as a first approximation the term

$\frac{3GMu^2}{c^2}$ can be ignored in solving Eq. 324 and hence we solve the equation

$$\frac{d^2u}{d\phi} + u = 0 \text{ instead.}$$

The solution of the latter equation is

$$u = \frac{1}{r} = \frac{\cos\phi}{d} \quad \left(-\frac{\pi}{2} < \phi < \frac{\pi}{2}\right) \quad (325)$$

where d is a constant.

As we will see, d represents the distance of closest approach of the light ray to the center of gravitating object and hence in the case of grazing ray it represents the radius (or radial coordinate) of the gravitating star.

We should note that the solution can also be given as $\boxed{u = \frac{\sin\phi}{d}}$ with $0 < \phi < \pi$.

In fact, for a polar coordinate system in a standard form (i.e. where ϕ is the angle that $r\,e_r$ makes with the positive x axis of the corresponding Cartesian system) $\boxed{u = \frac{\cos\phi}{d}}$ represents a straight line parallel to the y-axis and intercepting the x axis at d (see Figure 9) while

$\boxed{u = \frac{\sin\phi}{d}}$ represents a straight line parallel to the x-axis and intercepting the y axis at d.

Pág. 338(339) - §10 - the curvature and torsion of a space curve.

Fig. 63

Given a curve S in three-dimensional Euclidean space.

We assume that S is the path of a point M moving with unit velocity, that is to say, during unit time it traverses an arc of S whose length is equal to unity.

Under this condition, the time spent is numerically to the length of the path traversed.

Denote the length by s and view it as an independent argument.

Denote by t the vector of instantaneous velocity of M.

We can consider it to be a unit vector:

$$(t, t) = 1 \qquad (1)$$

It lies along a tangent to the curve S in the direction of motion and is called the tangent vector.

If the line is not straight, then t changes its direction in space. Therefore, the point M experiences

an acceleration equal to the derivative of the velocity vector, or t'_s.

It can be proved that the scalar product of vectors is differentiated by the same rule as a product of functions.

Differentiating (1) with respect to s, we find that the acceleration is orthogonal to the velocity:

$$(t, t)'_s = 2(t, t'_s) = 0$$

Putting $k(s) = |t'_s|$ and assuming that $k(s) \neq 0$, we introduce the unit vector n, which is coincident in direction with t'_s (Fig. 63). Then

$$t'_s = kn \qquad (2)$$

k is called the curvature of the curve at the given point M.

By definition, $k \geqslant 0$.

Vector n is called the principal normal vector, while the plane passing through M parallel to vector t and n is termed the

osculating plane of the space curve S at the point M.

Let us construct the unit vector

$$b = [t \times n].$$

It is perpendicular to the osculating plane and is called the binormal vector at the point M (Fig. 63).

Pág. 339(340) – the basis t, n, b is called a trihedral (or moving trihedral).

Cálculo de la distancia entre dos puntos en el plano de Lobachevski

Pág. 438 (439) – Fig. 159.

Fig. 159

orisfera Σ (es la geometría de Euclides (§47).

Un punto arbitrario M del plano α le corresponda un punto M' de la orisfera Σ, en el cual ésta se intersecará con la recta que pasa por M paralelamente a la perpendicular trazada a α en el punto O (fig. 159; la dirección de paralelismo se supone establecida hacia el mismo sentido desde el plano α en que está situada la orisfera Σ).

Fácilmente se comprende que las imágenes de todos os puntos del plano α no llenan la orisfera Σ por completo.
(llenar-preencher)

En el plano α consideremos alguna recta OA que pase por el punto O; sea ON la perpendicular al plano α en el punto O (el punto N se encuentra en el mismo lado respecto a α que la orisfera Σ).

En la bisectriz del ángulo AON, tracemos un segmento l de modo que le corresponde un ángulo de paralelismo $\Pi(l) = \frac{\pi}{4}$; denotemos con la

letra L el extremo de dicho segmento.

Debido a la elección de la magnitud de l, la recta u perpendicular al segmento OL en su extremo L y perteneciente al plano del ángulo AON, será paralela con respecto al rayo OA hacia un lado, y lo será con respecto al ON hacia el otro (fig. 159). Como la recta u es paralela a ON, es el eje de la esfera Σ y, por consiguiente, intersecará a Σ en cierto punto T.

Ahora, en el rayo OA tomemos un punto arbitrario M (distinto al O), trazando a través de él un rayo paralelo con respecto a ON. Este rayo pasa por el plano AON entre las rectas paralelas TL y ON. Por consiguiente, el punto M', en el cual el mismo atraviesa el círculo OT, se halla entre los puntos O y T. Por otro lado, si tomamos un punto cualquiera P' en el círculo OT entre O y T, trazando a través del mismo una recta paralela a la ON, desde O hacia N, aquélla será

paralela a la recta u en la misma dirección; en la otra dirección, esta recta se desviará de la recta u hacia el rayo OA, interseccándolo en un punto P. Esto significa que cada punto del círculo OT que se encuentre entre O y T es la imagen de un cierto punto perteneciente al rayo OA.

Por fin, queda claro que el punto O corresponde a sí mismo.

Así pues, las imágenes de todos los puntos del rayo OA llenan el arco del círculo OT con un extremo excluido T.

De aquí concluimos directamente que las imágenes de todos los puntos del plano α llenan sobre la esfera Σ un dominio "cubierto" por el arco OT (con el extremo T excluido) al girar éste alrededor de la recta ON.

Desde el punto de vista de la geometría, sobre la esfera este dominio constituye nada más que el recinto interior del círculo K, cuyo centro es el punto O, y cuyo radio es el arco del círculo OT. El arco OT se llama radio de curvatura del espacio de

Lobachevski. Si elegimos algún arco del círculo por concepto de la unidad de medida de las longitudes sobre la esfera Σ, entonces la longitud del arco OT se expresará por un cierto número R. El número R (con la escala elegida) lo llamaremos también radio de curvatura.

Pág. 439 (440) – si x es cualquier segmento que se halla dentro de E, el ángulo del paralelismo $\Pi(x)$ tiende uniformemente a $\frac{\pi}{2}$ para $R \to \infty$ (véase el § 230). (Pág. 476 (477)).

En el caso límite de $R = \infty$ el círculo K se extiende sobre toda la esfera Σ, pero entonces la esfera Σ coincide con el plano α, resultando euclidiano el espacio.

... $x'^2 + y'^2 = R$.

Sistema de coordenadas sobre el plano de Lobachevski α. Esto es, con cada punto M del plano α compararemos, por concepto de coordenadas, dos números

$\Rightarrow$

$$x = \frac{x'}{R}, \quad y = \frac{y'}{R},$$

donde x' y' son las coordenadas cartesianas de la imagen M' del referido punto sobre la esfera Σ.

De lo antecedente se deduce que las coordenadas de cualquier punto del plano α satisfacen la desigualdad

$$x^2 + y^2 < 1;$$

recíprocamente, si dos números x, y dados con anterioridad satisfacen tal desigualdad, entonces sobre el plano α existe un punto (exactamente uno), cuyas coordenadas son los mismos números x, y dados.

Los números x, y se llaman coordenadas beltramianas del punto M.

Pág. 292 (293) – However, we can seek a better solution by substituting this approximate solution into the u^2 term of Eq. 324, that is

$$\frac{d^2u}{d\phi^2} + u = \frac{3GM\cos^2\phi}{c^2d^2}$$

It can be easily verified that a solution of the last equation is:

$$u = \frac{\cos\phi}{d} + \frac{GM(2-\cos^2\phi)}{c^2d^2}$$

Now, to find the total deflection of the light ray during its journey from infinity (i.e. $r \to \infty$) on one end (to) (de um lado) to infinity on the other end (i.e. from $u=0$ at the source of light to $u=0$ at the detector of light), we set $u=0$ in the last equation and

find the difference between ϕ at one end and ϕ at the other end, that is:

$$\frac{\cos\phi}{d} + \frac{GM(2-\cos^2\phi)}{c^2 d^2} = 0$$

$$\frac{\cos\phi}{d} + \frac{2GM}{c^2 d^2} - \frac{GM\cos^2\phi}{c^2 d^2} = 0$$

$$\frac{GM}{c^2 d}\cos^2\phi - \cos\phi - \frac{2GM}{c^2 d} = 0 \qquad (326)$$

Pag. 293 (294) →

Figure 9: A simple sketch depicting the deflection of a light ray emitted from a light source LS as the ray passes by a gravitating body GB (which is at the origin of

coordinates) toward a light detector LD and hence the light ray is deflected by an angle $\delta\phi$ causing the image of LS to be visually displaced and thus it is seen at an apparent location AL. The other symbols in the sketch are explained in the text.

Now, if we note that $\frac{GM}{c^2 d}\cos^2\phi$ is very small for a light ray grazing a typical star then we can ignore this term

Obs: Wrong!!!

Aqui está o problema, nós devemos observar que este "pequeno" ajuste ou um certo tipo de arredondamento ou cancelamento prejudica todo o cálculo pois esta ação gera um efeito em cadeia nos cálculos. O mais grave, é que este falso ajuste gera um erro de cálculo na obtenção do valor do Pi, agora com o meu ajuste, nós obtemos M.U.S. (Mathematical Uniforme Space)

Nós não podemos admitir qualquer ajuste ou omissão de qualquer valor no cálculo desta equação.

Return:

We can...

$\frac{GM}{c^2 d} \cos^2\phi$ is very small for a light ray.

$G = 6.674 \times 10^{-11}$

$M = 1.989 \times 10^{30}$

$c = 3 \times 10^{8}$

$r = 6.9551 \times 10^{8}$

obs:

$$u = \frac{1}{r} = \frac{\cos\phi}{d} \quad \left(-\frac{\pi}{2} < \phi < \frac{\pi}{2}\right)$$

off:

$d = 6.9551 \times 10^{8}$

IMPORTANT:

Calcular o valor correto

$$\frac{GM}{c^2 d} \cos\phi$$

obs: Utilizar no M.U.S.

Return: We can ignore this term (Wrong!!!) ?

and hence we get an approximate equation:

$$-\cos\phi - \frac{2GM}{c^2 d} \simeq 0$$

whose solution is:

$$\cos\phi \simeq -\frac{2GM}{c^2 d} \qquad (327)$$

and hence:

$$\phi_1 \simeq \frac{\pi}{2} + \frac{2GM}{c^2 d} \text{ and } \phi_2 \simeq \frac{\pi}{2} - \frac{2GM}{c^2 d} \qquad (328)$$

These two possible values of ϕ correspond to the two ends of the light ray (i.e. source of light at infinity on one end and detector of light at infinity on the other end).

In fact, the value

$$\phi_2 \simeq \frac{\pi}{2} - \frac{2GM}{c^2 d}$$ corresponds to

$$\phi \simeq -\frac{\pi}{2} - \frac{2GM}{c^2 d}$$ or similarly to

$$\phi \simeq \frac{3\pi}{2} - \frac{2GM}{c^2 d}$$ (see Figure 9)

and that is why it does not give the correct sign.

More justification is given in the upcoming note 2 in the end of this answer. # (see)

Now, if we take the difference between ϕ at infinity on one end where the light source is located and ϕ at infinity on the other end where the light detector is located (see Figure 9) then we get the total deflection, that is:

$$\delta\phi = \phi_1 - \phi_2$$

$$\simeq \frac{\pi}{2} + \frac{2GM}{c^2 d} - \left(\frac{\pi}{2} - \frac{2GM}{c^2 d}\right) = \frac{4GM}{c^2 d}$$

which is the general relativistic formula that is given in the text (see Eq. 323).

Note 1: the reader may feel uncomfortable about the last approximation where we discarded the term

$$\frac{GM}{c^2 d}\cos^2\phi.$$

So, we show in this note

that this approximation is very good. Eq. 326 (which can be written as

$$GM\cos^2\phi - c^2 d\cos\phi - 2GM = 0)$$

is a quadratic equation in $\cos\phi$ and hence from the quadratic formula we get:

$$\cos\phi = \frac{c^2 d \pm \sqrt{c^4 d^2 + 8G^2M^2}}{2GM} \quad (329)$$

It is obvious that the root with plus sign is unacceptable because it is too large hence it should be rejected since

$$-1 \leq \cos\phi \leq +1.$$

Now, if we consider a grazing light ray and use the Sun as a typical star then from the approximate root (i.e. Eq. 327) we get:

$$\cos\phi \simeq -\frac{2GM}{c^2 d} \simeq$$

$$\frac{2 \times 6.674 \times 10^{-11} \times 1.989 \times 10^{30}}{(3\times10^8)^2 \times 6.9551 \times 10^8} \simeq$$

$\Rightarrow$

$$\simeq -4.2413596 \times 10^{-6}$$

While from the exact root (i.e. Eq. 329 with the minus sign), we get:

$$\cos\phi = \frac{c^2 d - \sqrt{c^4 d^2 + 8G^2M^2}}{2GM} \simeq$$

$$\simeq 4.2413599 \times 10^{-6}$$

As we see, the approximate root is virtually identical to the exact root.

Note 2: the transition from Eq. 327 to Eq. 328 may not be obvious.

However, we should note first that we have two different solutions because the original equation is quadratic and although (emboia) we already rejected one root on mathematical basis we should admit the existence of two physical roots. In fact, we can demonstrate formally that ϕ_1 and ϕ_2 of Eq. 328 are the principal solutions, but instead we can follow a simpler approach by using the trigonometric identity $\cos(\alpha \pm \beta) =$

trigonometric identity

$$\cos(\alpha \pm \beta) = \cos\alpha \cos\beta \pm \sin\alpha \sin\beta$$

with the sine approximation of small angle (i.e. $\sin\beta \simeq \beta$) to conclude that ϕ_1 and ϕ_2 in Eq. 328 produce Eq. 327

(and hence ϕ_1 and ϕ_2 are solutions to Eq. 327), that is:

$$\boxed{\cos\phi_1} = \cos\left(\frac{\pi}{2} + \frac{2GM}{c^2 d}\right) =$$

$$\cos\frac{\pi}{2}\cos\frac{2GM}{c^2 d} - \sin\frac{\pi}{2}\sin\frac{2GM}{c^2 d}$$

$$\simeq -\frac{2GM}{c^2 d}$$

$$\boxed{\cos\phi_2} = \cos\left(\frac{3\pi}{2} - \frac{2GM}{c^2 d}\right) =$$

$$\cos\frac{3\pi}{2}\cos\frac{2GM}{c^2 d} + \sin\frac{3\pi}{2}\sin\frac{2GM}{c^2 d}$$

$$\simeq \frac{2GM}{c^2 d}$$

where we used the aforementioned alternative expression for ϕ_2 (to

obtain the correct sign) and where the smallness of $\frac{GM}{c^2 d}$

(and hence $\frac{2GM}{c^2 d}$ is justified in exercise 7.

Note 3: the provision

$$\boxed{u \gg \frac{3GMu^2}{c^2}}$$

can be justified more generally by the following:

$$\frac{3GMu^2}{c^2 u} = \frac{3GMu}{c^2} = \frac{3GM}{c^2 r} =$$

$$= \frac{3}{2}\frac{2GM}{c^2 r} = \frac{3}{2}\frac{R_s}{r}$$

where R_s is the Schwarzschild radius and r represents the star radius (or radial coordinate) or larger.

Now, for ordinary stars $R_s \ll r$ and hence the provision is justified.

The reader should note that the "grazing" condition that associates this provision (and its alike) in the above derivation represents the worst case and hence the provision

becomes stronger in the non-grazing case.

Note 4: The validity of the above derivation should be restricted to the weak gravitational field case where the spacetime is approximately flat. This may be suggested by a number of indications such as (tal como) defining d as "distance", using polar coordinates (also see exercise 5) and accepting straight line solution as a first approximation (which is based on $\boxed{u \gg \frac{3GMu^2}{c^2}}$ and the smallness of $\boxed{\frac{GM}{c^2 d}}$). In fact, this restriction should be suggested by the question itself since "stars" usually generate weak gravitational fields (if we exclude neutron stars). This is also suggested by the use of terms like "typical star" and "ordinary star" (as well as other indications in the solutions of the upcoming Exercises).

Note 5: The above derivation

is based on a number of approximations and compromising assumptions (e.g. classical gravitational systems of weak gravity). Accordingly the derived formula should have limited validity from these perspectives (at least as far as this derivation is concerned).

Note 6: We defined d as the distance of closest approach, But considering the initial straight-line solution, it should be more appropriate to define it as the distance of impact (or impact parameter) where the supposed straight line is defined by the initial direction of the ray. However, we adopted as possible case of comparison to the upcoming classical derivation; see exercise 8). Anyway, for the considered weak gravitational field case (where the deflection of light is very tiny) the difference between the two definitions should be practically negligible. (insignificante)

→

Pág. 295 (296) – Exercises

2. Accordingly, accelerating frames are considered as compositions of series of inertial frames (i.e. instantaneous rest frames) where the deflection of light increases gradually as the speed of the frame increases. 370

[370] → However, we should note that it is not true in general that the observations in an accelerating frame are the same as the observations in the instantaneous (inertial) rest frame (see for example § 10.1.1).

3. What is the significance of light bending by gravity?

Since we have no gravitated mass then we should also have no gravitating mass (as such) and therefore gravity is an effect of the spacetime geometry (which is the result of the mass-energy distribution) rather than (sensu stricto) a force in a technical sense.

... the bending of light by gravity can be derived in classical physics

(although it is quantitatively different to that of general relativity) and hence it is consistent with the theoretical framework of Newtonian gravity and its paradigms (such (tol (ons) as force and gravitational field) despite potential reservations on some derivation methods.

4. Show that $u = \frac{\cos\phi}{d}$ is a solution to the equation

$$\frac{d^2u}{d\phi} + u = 0$$

<u>Answer</u>:

This can be easily shown by inserting $u = \frac{\cos\phi}{d}$ into the equation $\frac{d^2u}{d\phi} + u = 0$,

that is:

$$\frac{d^2u}{d\phi^2} + u = -\frac{\cos\phi}{d} + \frac{\cos\phi}{d} = 0$$

5. Verify that (a) the polar equation

$$\frac{1}{r} = \frac{\cos\phi}{d} \quad \left(\text{with } -\frac{\pi}{2} < \phi < \frac{\pi}{2}\right)$$

is an

equation of a straight line parallel to the y axis,

(b) the polar equation $\frac{1}{r} = \frac{\sin\phi}{d}$ (with $0 < \phi < \pi$) is an equation of a straight line parallel to the x axis.

Answer:

The transformation equations between polar coordinates (i.e. r and ϕ) and Cartesian coordinates (i.e. x and y) are:

$$r = \sqrt{x^2+y^2} \quad \cos\phi = \frac{x}{\sqrt{x^2+y^2}}$$

$$\sin\phi = \frac{y}{\sqrt{x^2+y^2}}$$

a) Transforming from polar coordinates to Cartesian coordinates we get:

$$\frac{1}{r} = \frac{\cos\phi}{d}$$

$$\frac{1}{\sqrt{x^2+y^2}} = \frac{x}{d\sqrt{x^2+y^2}}$$

$$x = d$$

which is the Cartesian equation of a straight line parallel to the y axis and intercepting the x axis at d.

b) Transforming again from polar to Cartesian we get:

$$\frac{1}{r} = \frac{\sin\phi}{d}$$

$$\frac{1}{\sqrt{x^2+y^2}} = \frac{y}{d\sqrt{x^2+y^2}}$$

$$y = d$$

which is the Cartesian equation of a straight line parallel to the x axis and intercepting the y axis at d.

6. Verify that:

$$u = \frac{\cos\phi}{d} + \frac{GM(2-\cos^2\phi)}{c^2 d^2} \qquad (330)$$

is a solution to the following equation:

$$\frac{d^2u}{d\phi^2} + u = \frac{3GM\cos^2\phi}{c^2 d^2} \qquad (331)$$

Answer:

We have

(equations) $\Rightarrow$

$$\frac{du}{d\phi} = -\frac{\sin\phi}{d} + \frac{2GM\cos\phi\sin\phi}{c^2 d^2}$$

$$\frac{d^2u}{d\phi^2} = -\frac{\cos\phi}{d} - \frac{2GM\sin^2\phi}{c^2 d^2} + \frac{2GM\cos^2\phi}{c^2 d^2} \quad (332)$$

Pág. 297

On substituting from Eqs. 332 and 330 into the left hand side of Eq. 331, we get:

$$\frac{d^2u}{d\phi^2} + u = -\frac{\cos\phi}{d} - \frac{2GM\sin^2\phi}{c^2 d^2} + \frac{2GM\cos^2\phi}{c^2 d^2} + \frac{\cos\phi}{d} + \frac{GM(2-\cos^2\phi)}{c^2 d^2}$$

$$= -\frac{2GM\sin^2\phi}{c^2 d^2} + \frac{2GM\cos^2\phi}{c^2 d^2} + \frac{2GM}{c^2 d^2} - \frac{GM\cos^2\phi}{c^2 d^2}$$

$$= -\frac{2GM(1-\cos^2\phi)}{c^2 d^2} + \frac{2GM\cos^2\phi}{c^2 d^2} + \frac{2GM}{c^2 d^2} - \frac{GM\cos^2\phi}{c^2 d^2}$$

$$= -\frac{2GM}{c^2 d^2} + \frac{2GM\cos^2\phi}{c^2 d^2} + \frac{2GM\cos^2\phi}{c^2 d^2} +$$

$$\frac{2GM}{c^2 d^2} - \frac{GM\cos^2\phi}{c^2 d^2}$$

$$= \frac{3GM\cos^2\phi}{c^2 d^2}$$

which is the right hand side of Eq. 331 and hence Eq. 330 is a solution to Eq. 331.

7. Show that for a light ray grazing a typical star,

$$\boxed{\frac{GM}{c^2 d}\cos^2\phi}$$

is very small (i.e. close to zero).

Answer:

Let use the Sun as a typical star. So, for a light ray grazing the Sun, we have:

$$\frac{GM}{c^2 d} \simeq \frac{6.674\times10^{-11}\times1.989\times10^{30}}{(3\times10^8)^2\times6.9551\times10^8}$$

$$\boxed{\simeq 2.121\times10^{-6}}$$

Moreover, according to our setting

(i.e. the light ray follows a path oriented along the y-axis orientation with very small deflection)

$$\phi \simeq \frac{\pi}{2} \text{ and hence } \cos^2\phi \simeq 0.$$

Accordingly, $\frac{GM}{c^2 d}\cos^2\phi$ is very small.

Note: the smallness of $\frac{GM}{c^2 d}$ can be verified more generally as follows:

$$\frac{GM}{c^2 d} = \frac{1}{2}\frac{2GM}{c^2 d} = \frac{1}{2}\frac{R_s}{d}$$

where R_s is the Schwarzschild radius. Now, for ordinary stars $R_s \ll d$ and hence $\frac{GM}{c^2 d}$ is very small.

---

8. Derive a classical for light bending by stars (e.g. Sun) and hence show that the classical deflection is half the general relativistic deflection.

Answer: Let have a corpuscule of light whose mass is m and whose speed at

infinity (i.e. very far away from the gravitating body) is c and hence its classical total energy (i.e. kinetic plus potential) is

$$E = \frac{1}{2} mc^2 > 0.$$

Now according to classical mechanics the orbit of this corpuscle in the gravitational field of a gravitating body is a hyperbola with the gravitating body being at one of its loci. [372]

[372] → In classical mechanics, the shape of the orbit of a gravitated body is

elliptic if $E < 0$,

parabolic if $E = 0$ and

hyperbolic if $E > 0$.

Due to the conservation of total energy (i.e. kinetic plus potential) in the conservative gravitational field the total energy of this corpuscle along its orbital path remains constant, i.e. $E = \frac{1}{2} mc^2$! Moreover, in

classical mechanics the relation between the total energy E of a gravitated object of mass m that follows a hyperbolic path in the gravitational field of a gravitating object of mass M and the transverse semi-axis a of its hyperbolic path is given by:

$$E = \frac{GMm}{2a} \quad \text{that is} \quad a = \frac{GMm}{2E} \tag{333}$$

Referring to Figure 10, we have

$$\tan\left(\frac{\delta\phi}{2}\right) = \frac{a}{b} = \frac{GMm}{2Eb} = \frac{GMm}{mc^2 b} = \frac{GM}{c^2 b}$$

where b is the conjugate semi-axis of the hyperbolic path and where in step 2 we substituted from Eq. 333 while in step 3, we used $E = \frac{1}{2} mc^2$. Now, if we consider that the deflection of light by gravity in classical systems is very tiny (i.e. $\delta\phi$ is very small) then we can use the tangent approximation for small angles in the last equation, that is:

$$\tan\left(\frac{\delta\phi}{2}\right) \simeq \frac{\delta\phi}{2} = \frac{GM}{c^2 b} \quad \text{that is}$$

$$\delta\phi \simeq \frac{2GM}{c^2 b}$$

Figure 10.

<u>Figure 10</u>: A simple sketch depicting the deflection of a light ray LR emitted from a light source LS as the ray passes by a gravitating body GB toward a light detector LD and hence the ray is deflected by an angle $\delta\phi$ causing the image of LS to be visually displaced and thus it is seen at an apparent location AL. The other symbol in the sketch are explained in the text.

Pág. 298 (299) –

To compare this classical formula with the general relativistic formula (i.e. $\delta\phi \simeq \frac{4GM}{c^2 d}$) we need to find the relation between b and d. Now, d in the general relativistic setting is the distance of closest approach and hence it corresponds in the classical setting to the distance the focus (where the gravitating body is located) and the vertex of the hyperbolic branch that represents the path (see Figure 10). Accordingly, we should have:

$$d = \sqrt{a^2+b^2} - a \qquad (334)$$

$$d + a = \sqrt{a^2+b^2}$$

$$(d+a)^2 = a^2 + b^2$$

$$d^2 + 2da + a^2 = a^2 + b^2$$

$$d^2 + 2da = b^2$$

$$b = \sqrt{d^2 + 2da}$$

$$b = d\sqrt{1 + 2(a/d)}$$

where we used standard relations from

the geometry of hyperbola (the unfamiliar reader should refer to the literature of conic sections).

Now, since the deflection is very tiny (and hence the hyperbola is highly eccentric) then from the properties of hyperbola we should have

$a \ll d$ and hence $(a/d) \simeq 0$

and $b \simeq d$, that is

$$\delta\phi \simeq \frac{2GM}{c^2 d}$$

As we see, this classical deflection is half the general relativistic deflection, i.e. $\delta\phi \simeq \frac{4GM}{c^2 d}$.

Note: The implicit assumption of the variation of the speed of light over its path in the gravitational field (because the conservation of the variation of the speed of light over its path in the gravitational field (because the conservation of kinetic-plus-potential energy requires the speed of light to vary along its path as the potential varies along this path). ... We should also note that the approximation $b \simeq d$ may also be obtained (possibly more directly) from Eq. 334 because the tininess of the deflection means that $a \ll b$ and hence from Eq. 334, we can conclude that $d \simeq b$. 20231128200000 SHH.

20231129083000

Pág. 299 (300) →

10. Calculate the deflection of a light ray grazing the Sun.

Since the ray is grazing then d in the formula of light deflection represents the Sun radius (or radial coordinate ~~not~~ noting that the difference between the two is negligible in these classical systems) which is about 6.9551×10^8 m.

Accordingly:

$$\delta\phi = \frac{4GM}{c^2 d} \simeq \frac{4 \times 6.674 \times 10^{-11} \times 1.989 \times 10^{30}}{(3 \times 10^8)^2 \times 6.9551 \times 10^8}$$

$$\simeq 8.483 \times 10^{-6} \text{ rad} \simeq 1.7497 \text{ arcsec}.$$

This, of course, is the general relativistic value. The classical value is half this.

14. light deflection formula $\delta\phi$

$\frac{2GM}{c^2 d}$ in classical physics and

$\frac{4GM}{c^2 d}$ in general relativity.

15. Show formally that the deflection of a gravitational lens decreases with the

increase of the distance of closest approach of the deflected ray.

From the light bending formulae (i.e. $\delta\phi = \frac{4GM}{c^2 d}$ in general relativity and $\delta\phi = \frac{2GM}{c^2 d}$ in classical gravity).

We see that the angle of deflection $\delta\phi$ is inversely proportional to the distance of closest approach d (i.e. the farthest rays are least deflected).

This is unlike the bending of (convex) optical lenses where the deflection of ray is directly proportional to the distance of the deflected ray from the central axis (and this is behind the focusing nature of optical lenses).

16. Show that the deflection of light by gravity can be considerable only if the gravitating object is compact (e.g. black hole)

The relativistic and classical light bending formulae can be written (respectively) in terms of the Schwarzschild radius R_S of the gravitating object as:

$$\delta\phi = \frac{2R_s}{d} \quad \text{and} \quad \delta\phi = \frac{R_s}{d}$$

Now, since $R_s \ll d$ unless the gravitating object is compact (where d can be comparable to R_s) then the deflection can be considerable only if the gravitating object is compact.

17. Show that in gravitational lensing the lensed object cannot be observed when the distance of the observer from the lens is less than a certain amount, and give an estimate of this amount.

Because the distance of closest approach d has a minimum limit (which is the radius R of the lens) the lensed object cannot be observed when the distance D of the observer from the lens is less than a certain amount. In fact, we can make a rough estimation of this amount using the tangent approximation of small angle, i.e.

$$\delta\phi \simeq \tan(\delta\phi) \simeq d/D \text{ and}$$

hence:

$$D_m \simeq \frac{d_m}{\delta\phi_x} = \frac{c^2 R^2}{4GM} \quad \text{where}$$

D_m is the minimum distance between the observer an the lens (for successful observation), d_m is the minimum limit of d and $\delta\phi_x$ is the maximum possible deflection, and where in the second step we used the general relativistic formula $\delta\phi = \frac{4GM}{c^2 d}$

with $\delta\phi \equiv \delta\phi_x$ and

$$d \equiv d_m = R.$$

In fact, this estimation is based on other approximations and hence it should represent an order of magnitude estimation. However, all these approximations do not affect the main point which is the requirement of a minimum limit on the distance between the observer and the lens (for successfull observation).

Cassirer and Klein on the Geometrical Foundations of Relativistic Physics.

Abstract: Several studies have emphasized the limits of invariance-based approaches such as Klein's and Cassirer's when it comes to account for the shift (para a mundanos) from the spacetimes of classical mechanics and of special relativity to those of general relativity.

... derived from Riemann rather than Klein.

Pág. 91 (99) → Norton's suggestion is that Einstein's theory of gravitation shows a combination of these strategies:
While following Riemann in the determination of metrical properties, he relied on Klein, ~~info~~ Einsfar (enquanto) as he deprived his coordinate system of all but topological properties.

Pág. 92 (100) – 4.2.
Felix Klein's Argument from Projective Geometry.

In Norton's reconstruction, Klein's subtractive (–) approach was modeled on projective geometry and the geometries of metrical space of zero or constant curvature.

In 1871, he presented a model of non-Euclidean geometry based on the analytic treatment of projective geometry by means of the algebraic theory of invariants.

Klein used a projective metric first studied by Arthur Cayley to derive the three principal cases of geometries of metrical space of constant curvature, that is parabolic,

elliptic and hyperbolic (corresponding to a manifold of null, more or less than zero, respectively).[3]

[3] – Cayley in his "Sixth Memoir upon Quantics" (1859) had limited himself to show that his projective system included (Euclidean) metrical. Klein was the first to derive the non-Euclidean cases (i.e. elliptic and hyperbolic geometries).

Search: bending

Pág. 102 (119) —

We can introduce a bigger spacetime:
the spacetime of everything, and embed the spacetime of mathematics into the spacetime of everything as a subspace.

Now imagine a surface S such as the sphere S^2 embedded in the space $\mathbb{R}^3$.
There are two kinds of geometry of S. The extrinsic (or rather external?) geometry of the surface

S is concerned with the geometry and shape of S such as the bending or curvature with respect to the ambient space $\mathbb{R}^3$, and has probably been studied since antiquity (think of conic sections in the Greek mathematics).

It was Gauss who initiated the intrinsic geometry (or should we say "internal geometry"?) of the surface S.

Then Riemann vastly generalized the intrinsic geometry to higher dimensional abstract manifolds in his famous lecture "On the hypotheses which lie at the foundations of geometry"

3) Hilbert's list of 23 problems.

4) Probably to a lesser degree, Poincaré's use of the hyperbolic geometry in his works on Fuchsian functions, which put hyperbolic geometry into the main stream of mathematics,[32] before that the main interest was more philosophical, as Poincaré explained in his extensive self-analysis of his scientific works (Poincaré 1921, § II),[33] and his works in topology which have changed the landscape of mathematics in the twentieth century.

[32] → This use of the hyperbolic plane by Poincaré was a starting point of many great theories and major results in mathematics. For example, the hyperbolic plane is a special case of symmetric spaces introduced by E. Cartan, which are Riemannian manifolds whose curvature tensor has zero covariant derivative and include and are more general than

Riemannian manifolds with constant curvature

... and the uniformization of Riemann surfaces through surfaces of constant curvature, in particular hyperbolic surfaces, has also led to Thurston's geometrization program in geometry and topology, which has proved by Grigori Perelman in 2002-2003.

[33] - Here we are mainly (principalmente) talking about the specific non-Euclidean geometry given by the hyperbolic geometry but not the general non-Euclidean geometries. Otherwise, as José Ferreirós pointed out, it will be necessary to enter into extensive discussions related to philosophical issues and applications of non-Euclidean geometries in mathematical physics.

radius of curvature[1]

(Nauenberg, 1994; Brackenridge, 1995, pp. 79-85)

[1] → These methods are based on the fact that the normal component of force is

proportional to the speed squared and inversely proportional to the radius of curvature.

Pág. 132 (147) → 5.2
Propositions 39-41, Book 1.

They deal with the motion of a point mass in a spherically symmetric potential $V(r)$. The corresponding central force is

$$F = \frac{dV}{dr}\hat{r} \qquad (5.1)$$

where $\hat{r}$ is the unit vector pointing away from the centre of force. Without loss of generality we can assume that the mass is $m = 1$. Indeed, this is a one-body problem (a body attracted by a centre of force) and no use is made of the third law of motion.

5.2.1. Proposition 39

In Proposition 39 Newton considers a "body" moving in a straight line ADE under the action of a centripetal force (see Fig. 5.1)

He shows that the square of the speed is proportional to the area subtended under the curve that represents the variation of the force's intensity as

a function of distance.
In Fig. 5.1 a body is falling from rest in A towards the center of force C.

Klein and Lie on the Differential Geometry of Kummer Surfaces

Kummer surfaces, which arise naturally in line geometry, and quartics with a double conic curve. A special case of the latter had been studied by Gaston Darboux and Théodore Montard in the context

of sphere geometry.

When the double conic is the imaginary sphere-circle that lies on all spheres, Darboux showed that the lines of curvature of this quartic are algebraic curves of the 8th degree.

Using his mapping, Lie realized these curves must go over into asymptotic curves of degree 16 on the corresponding Kummer surface.

Pág. 181 (195) →

Asymptotic curves are only visible in regions of negative curvature as they are otherwise imaginary curves.

Bernhard Riemann

Thus, as for Gauss and Lobachevsky "space" for Riemann means physical space and geometry describes the metric relations of this space.

And like Gauss and Lobachevsky Riemann was willing (estava disposto) to entertain the possibility that Euclidean geometry does not give the best description

of physical space. Indeed (de facto) compared to Gauss and Lobachevsky, Riemann extended the a priori possible manifolds to manifolds with other dimensions than three and to manifolds that are described by a Riemannian metric that has varying curvature.

Pág. 329 (339) – 13.8

Beltrami's Real Substrate:

Beltrami is often given the honor of having proved the consistency of non-Euclidean geometry and thus the impossibility of proving the

parallel postulate.

This is true in the following sense:

On the basis of Gauss' intrinsic theory of surfaces, Beltrami showed in 1868 that the geometry on a surface with constant negative Gauss curvature is the same as Lobachevskian non-Euclidean geometry.

Schwab and his critics
(1743–1821)

In a 1791 issue of the journal, Schwab published a paper against Schultz, and offered an analytic proof of the fact that

$\boxed{\text{one side of a triangle is shorter than the sum of the other two.}}$

Pág. 528 (533) – Schwab →
He set himself no less an aim (also) than to resuscitate

$\boxed{\text{Leibniz' "analysis situs"}}$

and prove the PARALLEL POSTULATE.

Schwab's first work on the topic is a "Tentamen novae parallelarum theoriae", published in 1801, in which he presented his epistemological view and a new theory of parallel.

This was later supplemented by a longer essay in French, the "Essai sur la situation" from 1808, which

expounded Schwab's more general views about Leibniz's project of an analysis situs.

And finally by a Commentatio on the First Book of the Elements (1814), in which Schwab attempted to reform elementary geometry and prove all the axioms in Euclid. [46]

[46] → ... in a few of them he restated his geometrical examples and the theory of parallels.
Nonetheless (no entanto) he did not not write those eight volumes on the theory of parallel that De Morgan found somewhere attributed to him:
"Eight volumes on the theory of parallels? If there be such a work, I trust I and it never meet, though ~~never~~ ever so far produced" (De Morgan, 1915, Vol. 1, p. 230)

Book: De Morgan, A Budget of Paradoxes" → 1915.

→ 151 pages (1943) - Pág. 59(62)

Equal and similar triangles placed in paving alongside one another with their bases in one and the same straight line.

If a triangle be displaced in a plane along a straight line (without rotation), all its points, including those of its bounding lines, will describe equal paths.

The same bounding line will furnish, therefore, in any two different positions, a system of two straight lines equal distant from one another at all points, and the operation coincidently vouches (garantir) for the equality of the angles made by the line of displacement on corresponding sides of the two straight lines.

The sum of the interior angles on the same side of the line of displacement was consequently determined to be two right angles, and thus EUCLID'S theorem of parallel was reached.

→ wrong!!!

Obs: A solução depende da nova geometria e do novo (valor) numérico do π, que eu chamo M.U.S. (Mathematical Uniforme Space)

Neste caso, Fifth Postulate of Euclid or Parallel Postulate poderá haver duas soluções, uma paralela e a outra que (ela) as retas se interceptam dentro

do sistema de cálculo.

cont. Pag. 60(63) →

The sliding of a triangle along a ruler has remained to this day the simplest and most natural method of drawing parallel lines.

It is scarcely necessary to remark the theorem of parallel and the theorem of the angle-sum of a triangle are inseparably connected and represent merely different aspects of the same experience.

Pag. 74(77) –

If an oblique-angle triangle having the sides a, b, and c be displaced in the direction of the side b, only a and c will, by the principle above stated, describe equivalent parallelograms, which are alike in an equal pair of parallel sides on the same parallels. If a make with b a right angle, and the triangle be displaced at right angles to c the distance c, the side c will describe the square c^2, while the two other sides will describe parallelograms the combined areas of which are equal to the area of the square. But the two parallelograms are, by

the observation which just precedes, equivalent respectively to a^2 and b^2 — and with this the Pythagorean theorem is reached.

Fig. 11

The same result may also be attained by first sliding the triangle a distance a at right angle to a and then a distance b at right angles to b, where

$a^2 + b^2$ will be equal

to the sum of the surfaces swept out by c, which is obviously c^2.

Taking an oblique angle triangle, the same procedure just as easily and obviously gives the more general proposition,

$$c^2 = a^2 + b^2 - 2ab\cos\gamma.$$

Pag. 77(80) – Fig. 12

It is possible without a special angular measure to determine the straight line that cuts another straight line at right angles by making all its points equidistant from two points in the first straight line lying at equal distances from the point of intersection.

The bisector of an angle can be determined in a quite similar manner, and by continued bisection an angular unit can be derived of any smallness we wish.

A straight line parallel to another

straight line can be defined as one, all of whose can be translated by congruent curved or straight paths unite points of the first straight line[1].

[1] → If this form had been adopted, the doubts as to the Euclidean theorem of parallel would probably have risen much later.

Interessante !!!

Pág. 94(97) → Space and Geometry from the point of view of physical inquiry

Pág. 106(109) – Measure of Curvature, and Curvature of Space.

Gauss's measure of the curvature of a surface at any point is given by the expression

$$k = \frac{d\sigma}{ds} \quad \text{where}$$

ds is an element of the surface and

$d\sigma$ is the superficial element of the unit-sphere the limiting radii of which are

parallel to the limiting normals of the element ds.

This measure of curvature may also be expressed in the form

$$k = \frac{1}{\rho_1 \rho_2},$$

where ρ_1, ρ_2 are the radii of curvature of the surface at the point in question.

Of special interest are the surfaces whose measure of curvature for all points has the same value, — the surfaces of constant curvature.

Interessante!!!

Conceiving the surfaces as infinitely thin, non-distensible but flexible bodies, it will be found that surfaces of like curvature may be made to coincide by bending, as for example a plane sheet of paper wrapped round a cylinder or cone, but cannot be made to coincide with the surface of a sphere.

During such deformation, nay (no), even on crumpling, the proportional parts of figures

drawn in the surface remain invariable as to lengths and angles, provided we do not go out of the two dimensions of the surface in our measurements.

Conversely (por outro lado), likewise (da mesma forma), the curvature of the surface does not depend on its conformation in the third dimension of space, but solely upon its interior proportionalities.

Riemann now conceived the idea of generalizing the notion of measure of curvature and applying it to spaces of three or more dimensions.

Conformably thereto, he assumes that finite unbounded spaces of constant positive curvature are possible corresponding to the unbounded but finite two-dimensional surface of the sphere, while what we commonly take to be (infinite) infinite space would correspond to the unlimited plane of curvature zero, and similarly a third species of space would correspond to surfaces

of negative curvature.

Just as the figures drawn upon a surface of determinate constant curvature can be displaced without distortion upon this surface only (for example, a spherical figure on the surface of its sphere only, or a plane figure in its plane only), so should analogous conditions necessarily hold for spatial figures and rigid bodies.

The latter are capable of free motion only in spaces of constant curvature, as Helmholtz has shown at length.

Just as the shortest lines of a plane are infinite, but on the surface of a sphere occur as great circles of definite finite length, closed and reverting into themselves, so Riemann conceived in the three-dimensional space of positive curvature analogues of the straight lines and the plane as finite but unbounded.

Pág. 114 (117) –

Euclid's Fifth Postulate →

Fifth Postulate (also called the Eleventh Axiom and by some the Twelfth):

"If a straight line meet two straight lines, so as to make the two interior angles on the same side of it taken together less than two right angles, these straight lines being continually produced, shall at length meet upon that side on which are the angles which are less than two right angles".

IMPORTANT:

Euclid easily proves that if a straight line falling on two other straight lines makes the alternate angles equal to each other, the two straight lines will not meet but are parallel.

Obs: Com a nova geometria haverá uma prova qual que estas retas se encontrarão e ainda assim, continuarão paralelas dentro do contexto da nova matemática e do novo número pi; M.U.S. < pi.

But for the proof of the converse (prova do universo), that parallels make equal alternate angles with every straight line falling on them, he is obliged to resort to the Fifth Postulate.

This converse is equivalent to the proposition that only one parallel to a straight line can be drawn through a point.

Further, by the fact that with the aid of this converse it can be proved that the sum of the of the angles of a triangle is equal to two right angles and that from this last theorem again the first follows, the relationship between the propositions in question is rendered distinct and the fundamental significance of the Fifth Postulate for Euclidean geometry is made plain.

IMPORTANT:

Com a nova geometria hiperelíptica, a soma dos ângulos de um triângulo será diferente do valor de dois ângulos retos.

Pág. 116 - Saccheri's Theory of Parallels.
(119)

Fig. 16

Let us consider, for example, two congruent isosceles triangles ABC, DBC having right angles at A and D (Fig. 16), and let them be laid together at their hypothenuses BC so as to form the equilateral quadrilateral ABCD.

The first twenty-seven propositions of Euclid do not suffice to determine the character and magnitude of the two equal (right) angles at B and C.

Obs: Estes ângulos serão diferentes, ou seja, estes ângulos terão um outro número em decorrência da geometria hiperelíptica.

For measure of length and measure of angle are fundamentally different and directly not comparable; hence the first propositions regarding

the connection of sides and angles are qualitative only, and hence the imperative necessity of a quantitative theorem regarding angles, like that of the angle-sum.

Be it further remarked that theorems analogous to the twenty-seven planimetric propositions of Euclid may be set up for the surface of a sphere and for surfaces of constant negative curvature and that in these cases the analogous construction gives respectively obtuse and acute angles at B and C.

Obs: surface of a sphere → obtuse
surface of constant negative curvature → acute.

Saccheri → Book

Euclides ab omni nævo vindicatus. Milan, 1733.
German translation in Engel and Staeckel's Die Theorie der Parallelinien. Leipsic, 1895.

Pág. 117 (120) – Saccheri

If the Fifth Postulate is involved in the remaining assumption of Euclid,

then it will be possible to prove without its aid that in the quadrilateral ABCD (Fig. 17) having right angles at A and B and AC = BD, the angles at C and D likewise (hamzein) are right angles.

And, on the other hand, in this event, the assumption that C and D are either obtuse or acute will lead to contradictions.

Fig. 17

Saccheri, in other words, seeks to draw conclusions from the hypothesis of the right, the obtuse, or the acute angle.

He shows that each of these hypotheses will hold in all cases if it be proved to hold in one. It is needful to have only one triangle with its angles $\lesseqgtr 2R$ in order to demonstrate the universal validity of the hypothesis of the acute, the right, or the obtuse angle.

cont... 2023113022160 0 [illegible]

20231201071000

Pag. 118 (121) →

If a line (Fig. 17) join the two extremities of equal perpendiculars erected on a straight line AB, and the perpendicular dropped on AB from any point N of the first line NM, be equal to CA = DB, then is the hypothesis of the right angle demonstrated to be correct.

Interessante!!!

Saccheri rightly does not regard it as self-evident that the line which is equidistant from another straight line is itself a straight line.

Think only of a circle parallel to a great circle on a sphere (pause)

↳ obs: Comentário:

De acordo com a nova geometria hiperelíptica, a própria esfera apresenta uma deformação intrínseca que altera todos os valores numéricos dos cálculos envolvidos na questão.

Return:

... great circle on a sphere which does not represent a shortest line on a sphere and the two faces of which cannot be made congruent.

See:

Other experimental proofs of the correctness of the hypothesis of the right angle are the following.

Fig. 18

If the angle in a semicircle (Fig. 18) is shown to be a right angle, $\alpha + \beta = R$, then is $2\alpha + 2\beta = 2R$, the sum of the angles of the triangle ABC.

Fig. 19.

If the radius be subtended thrice (3x) in a semicircle and the line joining the first and the fourth extremity pass through the center, we shall have at C (Fig. 19)

$3a = 2R$ $(2R)$

$\boxed{3a = 2R}$, and consequently each of the three triangles will have the angle-sum 2R.

Pág. 119 (122) → For (Fig. 20) if the angles at B and C give $\beta + \delta + \gamma + \epsilon = 4R$, so also is 4R the angle-sum of the quadrilateral BCB'C'.

Fig. 20 →

Fig. 20

For (Fig. 20) if the angles at B and C' give

$$\beta + \delta + \gamma + \epsilon = 4R,$$

so also is 4R the angle-sum of the quadrilateral $\boxed{BCB'C'}$.

Even Wallis (1663) based his proof of the FIFTH POSTULATE on the assumption of the existence of similar triangles, and a modern geometer, Delboeuf, deduced from the assumption of similitude the entire Euclidean geometry.

Interessante!!!

The hypothesis of the obtuse angle, Saccheri fancied he could easily refute.

But the hypothesis of the acute angle presented to him difficulties and in his quest for the expected contradictions he was carried to the most far-reaching conclusions, which Lobachévski and Bolyai subsequently rediscovered by methods of their own.

Ultimately he felt compelled to reject the last-named hypothesis as

incompatible with the nature of the straight line;
for it led to the assumption of different kinds of straight lines, which met at infinity, that is, had there a common perpendicular.

STOP: retornando a uma idéia que eu pensei

(... great circle on a sphere)
Saccheri → straight line (?)

See: think only a circle parallel to a great circle on a sphere which does not represent (interessante !!!)
a shortest line on a sphere and the two faces of which cannot be made congruent.

See:

→ circle parallel (a)
→ great circle (b)

Esses dois círculos estão paralelos na esfera E.

Nós devemos observar que os pontos A e B apresentam dois aspectos a serem descritos:

a) A e B estão sobre a superfície da esfera E e a distância entre estes pontos é descrito por meio de um arco;

b) A e B representam uma linha reta que passa pelo interior da esfera E, ligando estes dois pontos que estão na superfície da esfera E.

IMPORTANT !!!

De acordo com a nova geometria (~~elíptica~~) hiperelíptica, a distância entre os pontos A e B, serão diferentes ou melhor, será diferente das opções anteriores de modo que nem o arco e nem a linha reta representará a ligação ou distância real entre os pontos A e B.

~~Atenção~~ !!!

O fato de toda a esfera não ser perfeitamente esférica, ou seja, a distância entre o seu centro e um ponto sobre a sua superfície não ser a mesma em toda a superfície, gerará repercussões matemáticas importantes.

A distância entre o ponto A e B não será um arco perfeito e nem uma linha reta perfeita, havendo uma outra distância.

Interessante!!!

O cálculo será extremamente complexo pois a deformação da esfera alterará todas as distâncias na esfera tanto internamente quanto externamente.

O interessante nesta pesquisa, é que haverá linhas retas mas obtidas de forma indireta, ou melhor, linhas retas decorrentes dos cálculos de distâncias dos pontos iniciais A e B, que não será um arco ou uma linha reta.

A curvatura dupla elíptica ou geometria hiperelíptica é a responsável pela deformação da esfera ou de qualquer outro elemento em virtude das três forças fundamentais da física.

Return : Pág. 120 (123) →

..., for it led to the assumption of different kinds of straight lines, which

$\boxed{\text{met at infinity}}$, that is, had there a common perpendicular

Obs: Com a nova geometria hiperelíptica, nós podemos

observar que as linhas retas paralelas apresentarão um comportamento matemático geométrico diferenciado em relação à geometria Euclidiana e não-Euclidiana.

São duas hipóteses:

a) as linha retas paralelas se encontram na nova geometria, não apenas uma vez e não necessariamente apenas uma vez naquele ponto.

b) duas linhas retas não paralelas e com origem no mesmo ponto, poderão ser paralelas e também poderão se encontrarem em um ponto e não apenas uma vez.

Em resumo:

Haverá um paradoxo dualístico das retas paralelas e não paralelas.

Estas retas apresentarão um comportamento matemático e geométrico diferenciado dependendo do momento da análise do fenômeno geométrico. Localmente, estas retas poderão ser paralelas e não-paralelas, podendo o seu estado ser alterado de acordo com o momento da análise em uma fase posterior.

Os conceitos de linhas retas e paralelismo serão alterados na nova geometria hiperelíptica.

Pág. 120 (123) – Lambert's Investigations.

Lambert is allied in method to that of Saccheri.

The case of the obtuse angle, which requires the sum of the angles of a triangles to exceed 2R, he discovers to be realized in the geometry of spherical surfaces in which the difficulty of parallel lines entirely vanishes.

Interessante!!!

This leads him to the conjecture that the case of the acute angles, where the sum of the angles of a triangle is less than 2R, might be realized on the surface of a sphere of imaginary radius.

The amount of the departure of the angle-sum from 2R is in both cases proportional to the area of the triangle, as may be demonstrated by appropriately dividing large triangles into small triangles, which on (en que) diminution may be made to approach as near as we please to the angle-sum 2R.

Lambert advanced very

closely in this conception to the point of view of modern geometers.
Admittedly a sphere of imaginary radius,

$\boxed{r\sqrt{-1}}$ is not a visualizable geometric construct, but analytically it is a surface having a negative constant

GAUSSIAN measure of curvature.

Even GAUSS appears to have thought of a sphere of imaginary radius, as is obvious from his formula for the circumference of a circle (Letter to Schumacher, July 12, 1831).

obs: Yet in spite of all, Lambert actually fancied (imagined) he had approached so near to the proof of the Fifth Postulate (?) that what was lacking would be easily supplied.

Pág. 121 (124) →

View of Gauss

IMPORTANT: ⇒

"Gauss regarded geometry merely as a logically consistent system of constructs, with the

THEORY OF PARALLEL

placed at the pinnacle as an axiom; yet he had reached the conviction that this proposition could not be proved, though it was know from experience, for example, from the angles of the triangle joining the Brocken, Hohenhagen, and Inselsberg, that it was approximately correct.

atention!!

But if this axiom be not conceded, he contends (afirma), there results from its non-acceptance a different and entirely independent geometry, which he had once investigated, and called by the name of the

ANTI-EUCLIDEAN GEOMETRY

Such, according to Sartorius von Walfershausen,

was the view of Gauss.

Pág. 122 (125) — Researches of Stolz.

Fig. 21.

Stolz's brochure

On large triangle ABC having the angle-sum 2R.

We draw the perpendicular AD on BC, complete the figure by BAE ≅ ABD and CAF ≅ ACD, and add to the figure BCFAE the congruent figure CBHA'G.

#: O quadrado AEBD é igual ao (congruente) quadrado A'GCI, ou seja, basta colocar o mesmo quadrado AEBD no canto inferior direito

do retângulo (maior) EFGH.

We obtain thus a single rectangle, for the angles E, F, G, H are right angles and those at A, C, A', B are straight angles (equal to 2R), the boundary lines therefore straight lines and the opposite sides equal.

Pág. 123 (126) →

A rectangle can be divided into two congruent rectangles by a perpendicular erected at the middle point of one of its sides, and by continuing this procedure the line of division may be brought to any point we please in the divided side.

Fig. 22

And the same holds true of the other two opposite sides. It is possible, therefore, from a given rectangle

ABCD (Fig. 22) to cut out a smaller AMPQ having sides bearing any (tendo qualquer) proportion to one another.

The diagonal of this last divides it into two congruent right-angled triangles, of which each, independently of the ratio of the sides, has the angle-sum 2R.

Every oblique-angled triangle can by the drawing of a perpendicular be decomposed into right-angled triangles, each of which can again be decomposed into right-angled triangles having smaller sides, so that 2R, therefore, results for the angle-sum of every triangle if it holds true exactly of one.

Pág. 124 (127) → IMPORTANT !!!

Questionável, não se podendo afirmar de forma categórica em virtude da nova geometria hiperelíptica

See: By the aid of these proportions which repose on observation, we conclude easily that the two opposite sides of a rectangle

(or of any so-called parallelogram) are everywhere, no matter how far prolonged, the same distance apart, that is never intersect.

(wrong!!!)

They have the properties of the EUCLIDEAN PARALLEL, (?) and may be called and defined as such.

It likewise follows, now, from the properties of triangles and rectangles, that

> two straight lines which are cut by a straight line so as to make the sum of the interior angles on the same side of them less than two right angles will meet on that side, but in either direction from their point of intersection will move indefinitely far away from each other.
> The straight line therefore is infinite.

Pág. 125(128) – The Contributions of Lobachevski and Bolyai.

See: Engel and Staeckel

Urkunden zur Geschichte der nichteuklidischen Geometrie.

L. N. I. Lobatschefskij, Leipzig, 1899.

Pág. 126(129) – Lobachevski also undertook his investigations in the hope of becoming involved in contradictions by the rejection of the Euclidean axiom.

Obs: But after he found himself mistaken in this expectation, he had the intellectual courage to draw all the consequences from this fact.

From a point lying outside a straight line g (Fig. 23), a perpendicular p is dropped and through the same point in the plane

pq a straight line h is drawn, making with the perpendicular an acute angle s.

Fig. 23

Making tentatively the assumption that g and h do not meet but on the slightest diminution of the (menor diminuição) angle s they would meet, we are at once forced by the homogeneity of space to the conclusion that a second line K having the same angle s similarly deports itself on the other side of the perpendicular.

Hence all non-intersecting lines drawn through the same point are situate between h and K.

The latter form the boundaries between the intersecting and non-intersecting lines and are called by Lobachevski parallel.

→

Pág. 127 (130) - New Elements of Geometry (1835) - Lobachevski.

"parallel-angle" was very much less than a right angle, when on slight (leve) prolongation it could be distinctly seen that they would intersect.

... the illustration the variation of s from a right angle is so small that h and k are to the eye indistinguishably coincident.

Prolonging, now, the perpendicular p to a point beyond its intersection with h, and drawing through its extremity a new line l parallel to h and therefore parallel also to g, it follows that the parallel-angle s', must necessarily be less than s, if h and l are not again to fulfill (cumprir) the conditions of the Euclidean case.

Continuing in the same manner, the prolongation of the perpendicular and the drawing of parallels, we obtain a parallel angle that constantly decreases.

Considering, now, parallels which are more remote and consequently

converge more rapidly on the side of convergence, we shall logically be compelled to assume, not to be at variance with the preceding supposition, that on approach or on the decrease of the length of the perpendicular the parallel-angle will again increase.

The angle of parallelism,

Pág. 128 (131) -

the angle of parallelism, therefore, is an inverse function of the perpendicular p and has been designated by Lobachevski by

$$\boxed{\Pi(p).}$$

Fig. 24

A group of parallels in a plane has the arrangement shown schematically in Figure 24.

They all approach one another asymptotically toward the side of their convergence.

The homogeneity of space requires that every "strip" between two parallels can be made to coincide with every other strip provided it be displaced the requisite distance in a longitudinal direction.

If a circle be imagined to increase indefinitely, its radii will cease to intersect the moment the increasing arcs reach the point where the convergence of the radii corresponds to parallelism.

The circle then passes over into the so-called "boundary-line"

Similarly, will pass into what Lobachevski call a "boundary-surface".

The boundary-lines bear a relation to the boundary-surface analogous

to that which a great circle bears to the surface of a sphere.

The geometry of the surface of a sphere is independent of the axiom of parallels.

IMPORTANT: !!!

Pág. 129 (139) →

Esta afirmação parece correta, a priori, com base na matemática que nós temos hoje.

A geometria euclidiana e não-euclidiana pode utilizar esta afirmação sem maiores consequências em seus cálculos.

Com a nova matemática, geometria hiperelíptica, esta afirmação não tem mais viabilidade matemática. Desta forma há uma "contaminação" em todos os cálculos.

A nova geometria depende "em parte" do axioma dos paralelos, tanto para confirmá-la quanto para refutá-la, de acordo com os cálculos que estão em andamento.

(Atentar à nova realidade!!!)

Pág. 129 (132) → But since it can be demonstrated that triangles formed from boundary-lines on a boundary-surface no more exhibit an excess of angle-sum than do (finite) finite triangles on a sphere of infinite radius, consequently the

$\boxed{\text{rules of the Euclidean geometry}}$

likewise hold good for these boundary-triangles.

Fig. 25.

To find points of the boundary-line, we determine (Fig. 25) and a bundle of parallels,

$\alpha a, b\beta, c\gamma, d\delta \ldots$

lying in a plane points a, b, c, d in each of these parallels so situated with respect to the point a in $a\alpha$

point a in aa that
$\angle aab = \angle \beta ba$, $\angle aac = \angle \gamma ca$,
$\angle aad = \angle \delta da$...

Owing (dendo) to the sameness of the entire construction, each of the parallels may be regarded as the "axis" of the boundary line, which will generate, when revolved about this axis, the boundary-surface. For the same reason all boundary-lines and all boundary-surfaces are congruent.

The intersection of every plane with the boundary-surface is a circle.

It is a boundary-line only when the cutting plane contains the axis.

In the Euclidean geometry there is no boundary-line, nor boundary-surface.

The analogues of them are here the straight line and the plane.

If no boundary-line exists, then necessarily must any three points not in a straight line lie on a circle.

Hence the younger Bolyai was able to replace the Euclidean axiom by this last postulate.

Let aa, bB, $c\gamma$ be a system of parallel, and ae, a_1e_1, a_2e_2, ... a system of boundary-lines, each of which systems divides the other into equal parts (Fig. 25).

The ratio to each other of any two boundary-arcs between the same parallels, e.g., the arcs $ae = u$ and $a_2e_2 = u'$ is dependent therefore solely (exclusivamente) on their distance apart $aa_2 = x$.

We may put generally

$$\frac{u}{u'} = e^{\frac{x}{k}}$$

, where

k is so chosen that e shall be the base of the Naperian system of logarithms.

In this manner exponentials and by means of these hyperbolic functions are introduced.

For the angle of parallelism, we obtain

$$s = \cot \frac{1}{2} \Pi(p) = e^{\frac{p}{k}}.$$ If

$p = 0$, $s = \frac{\pi}{2}$; if $p = \infty$, $s = 0$.

An example will illustrate the relation of the Lobachevskian to the Euclidean and spherical geometries.

For a rectilinear Lobachevskian triangle having the sides a, b, c, and the angles A, B, C, we obtain, when C is a right angle,

$$\sinh \frac{a}{k} = \sinh \frac{c}{k} \sin A,$$

Here sinh stands for the hyperbolic sine,

$$\sinh x = \frac{e^x - e^{-x}}{2} \quad \text{whereas}$$

Pag. 131 (134)

$$\sin x = \frac{p^{xi} - e^{-xi}}{2i},$$

or,

$$\sinh x = \frac{x}{1!} + \frac{x^3}{3!} + \frac{x^5}{5!} + \frac{x^7}{7!} + \dots,$$

and

$$\sin x = \frac{x}{1!} - \frac{x^3}{3!} + \frac{x^5}{5!} - \frac{x^7}{7!} + \dots$$

Considering the relations $\sin(xi) = i(\sinh x)$, or
$\sinh(xi) = i \sin x$,
involved in the foregoing formulae, it will be seen that the above-given formula for the Lobachevskian triangle passes over into the formula holding for the spherical triangle,

$$\sin \frac{a}{K} = \sin \frac{c}{K} \sin A, \text{ when}$$

Ki is put in the place of K in the former and
K is considered as the radius of the sphere, which in the usual formulae assumes the value unity.

The re-transformation of the spherical formula into the Lobachevskian by the same method is obvious.

If K be very great in comparison with a and c, we may restrict ourselves to the first number of the series for sinh or sin, obtaining in both cases,

$$\frac{a}{K} = \frac{c}{K} \sin A \text{ or } a = c \sin A,$$

the formula of plane Euclidean geometry, which we may regard as a

limiting case of both the Lobachevskian and spherical geometries for very large values of K, or for $K = \infty$

$(K = \infty)$

It is likewise permissible to say that all three geometries coincide in the domain of the infinitely small.

Non-Euclidean Geometry.

Return : Pág. 54(74)

... Ernst Breitenberger (1984).
More recently, Jeremy Gray points out that Gauss called into question the necessity of Euclidean geometry because he focused on the problems concerning the definition of the plane and that of parallel lines.

However, he did not start with three-dimensional non-Euclidean space as Bolyai and Lobachevsky did (Gray 2006, p. 75).

Obs: Gray, Jeremy J. 2006. Gauss and non-Euclidean geometry.

On the other hand, Erhard Scholz defends the interpretation of GAUSS's measurement as an empirical test of Euclid's geometry in the following sense.

Even though Gauss could not have known non-Euclidean geometry at that time, his study of the geometric properties of surfaces enabled him to make heuristic assumptions about physical space.

Scholz interprets the limit of approximation in Gauss's experiment

as an informal counterpart of the upper limit of a measure of the curvature of space that is compatible with the results of measurement (Scholz 2004, pp. 364-365).

Pág. 55(75) – Therefore, Riemann developed the more general concept of manifold, which he introduced as an n-fold extended magnitude,

He (Riemann) thereby extended GAUSS's theory of surfaces to n-dimensional manifolds.

Gauss's theory admits such an (tal) extension because it enables the study of the intrinsic properties of surfaces, especially curvature, independently of the assumption of a surrounding, three-dimensional space.[4]

[4] ⇒ On Riemann's concept of manifold, see Torretti.

Pág. 57(77) - Manifolds of constant curvature, for example, can have an Euclidean or non-Euclidean metric. Riemann's supposition is that space is a continuous, threefold extended manifold which admits an

infinite number of possible geometries.

Pág. 58 (78) - According to Helmholtz, the free mobility of rigid bodies and the remaining facts underlying (subjacente) geometry (i.e. n-dimensionality and the monodromy of space) provide us with the necessary and sufficient conditions to obtain a Riemannian metric of constant curvature.

...

Furthermore, Riemann's conception of space differs from Helmholtz's conception because Riemann was not committed to the supposition that space is a manifold of constant curvature.

Riemann's conjecture was that the curvature of space might be variable at the infinitesimal level, provided that the total curvature for intervals of a certain size equal approximately zero.

Beltrami proved that such a surface provided an interpretation of Bolyai-Lobachevsky geometry.

Pág. 59 (79) →

Eugenio Beltrami (letter):

a) "Essay on an Interpretation of Non-Euclidean Geometry" (1868).

b) "Fundamental Theory of Spaces of Constant Curvature" (1869)

After reading Beltrami's letter, Helmholtz realized that if space is supposed to be a manifold of constant curvature, a choice has to be made between Euclidean and non-Euclidean geometry.
Helmholtz accounted for this generalization of the problem in the lecture gave in Heidelberg on 1870 on
"the Origin and Meaning of Geometrical Axioms".

Pág. 59(79)-

Helmholtz's argument was based on Beltrami's interpretation of Bolyai-Lobachevsky geometry on a pseudospherical surface, which is a surface of constant negative curvature.

Helmholtz extended Beltrami's interpretation to the three-dimensional case and described what would appear to be the conditions of motion in the imaginary world behind a convex mirror:

for every measurement in our world, there would be a corresponding measurement in the mirror.

Pág. 68(88) - 3.3.2.

Riehl's Arguments for the Homogeneity of Space

Riehl concluded that three-dimensionality depends on experience and restricted apriorricity to infinity, continuity, and homogeneity.

Pág. 85 (105) -

Helmholtz's solution depends on his distinction between the general properties of space (e.g., three-dimensionality and constant curvature), on the one hand, and further specifications,

including not only Euclidean axioms, but also the axioms of spherical and pseudospherical geometry (i.e., the other two cases of manifolds of constant curvature), on the other.

Pag. 86 (106) → Regardless (independentemente) of the fact that curvature is an intrinsec property of surfaces, Lord, similar to many of his contemporaries, believed that spherical or pseudospherical surfaces can only be characterized as constructions in three-dimensional Euclidean space.

Pág. 90 (110) – Helmholtz began with the most basic relationship between spatial magnitudes – namely, their congruence. The general properties of space, especially constant curvature, depend on the free mobility of rigid bodies, which is required for spatial magnitudes to be congruent.

Pág. 129 (149) – Klein used the theory of invariants

to show that the said geometries are equivalent to the three classical cases of manifolds of constant curvature studied by Eugenio Beltrami in the "Fundamental theory of Spaces of Constant Curvature". (1869)

Beltrami proved that non-Euclidean geometries apply to manifolds of constant curvature, in the case that the curvature is positive or negative, whereas (dagegen quo) the measure of curvature in a Euclidean surface equals 0.

Klein's classification showed that Euclidean geometry can be considered a limiting case of Non-Euclidean geometry: the transformation group relative to a manifold of zero curvature corresponds to parabolic geometry, which is the degenerate case, in which the points on the fundamental surface coincide.

Pag. 151 (170) - Chapter 6 ⇒

Euclidean and Non-Euclidean Geometries in the Interpretation of Physical Measurements.

Helmholtz had believed that he had shown that the free mobility of rigid bodies implied and was implied by a metric of constant curvature, which includes spherical and elliptic geometries.

Pág. 157 (176) - ...,

although (embora) Euclidean geometry was true or false, it was impossible to determine it empirically.

However, it does not follow that the truth or falsity of Euclidean geometry could not be determined empirically because Euclidean geometry was neither true nor false (see Griffin 1991, pp. 180-181)

⇒

Pág. 174 (193) –

However, Poincaré did not take into consideration the hypothesis of a manifold of variable curvature considered by Riemann.

For Poincaré, Riemannian geometries, ~~info~~ (infofar) insofar (enquanto) as they are ~~incomend~~ incompatible with the movement of a variable figure, can ever (pode sempre) be but purely analytical

(Poincaré 1902, pp. 47-48)

La science et l'hypothèse.

Interessante !!!

At that time, Poincaré could not know about Einstein's use of Riemann's geometry in general relativity.

...

For now, it is noteworthy (notável) that Poincaré's argument referred not so much to logically equivalent geometries, as to geometries that could be considered equivalent representations of physical reality.[26]

[26] → ...

Thus our experiences would be equally compatible with the geometry of Euclid and with a geometry of Lobachevski which supposed the curvature of space to be very small.

We choose the geometry of Euclid because it is the simplest.

Pág. 189 (208) - Chapter 7
Non-Euclidean Geometry and Einstein's General Relativity: Cassirer's View in 1921.

After Einstein's general relativity of 1915, even the assumption of constant curvature appeared to be restrictive.

Interessante!!!

This corresponds to the fact that the space-time continuum of general relativity is not conceived of as a background structure for the identification of physical events; the curvature of space-time in general relativity is variable and depends on the distribution of mass and energy.

Pág. 200 (219) –

Einstein posited himself between Helmholtz and Poincaré by arguing that geometry in the second of the meaning above (i.e., as a theory of space) is a branch of physics.

However, Einstein's physical geometry is inconsistent with the free mobility of rigid bodies.

The coordinating principle introduced by Einstein is the principle of equivalence.

Whereas the free mobility of rigid bodies is equally compatible with different specific geometries of constant curvature,

the principle of equivalence determines a univocal coordination between a single geometrical structure and physical reality.

The structure is that of a

FOUR-DIMENSIONAL SEMI-RIEMANNIAN

manifold of variable curvature.

The principle states that bodies affected only by gravitation follow geodesic trajectories in such a structure.

The presence of a gravitational field is represented by a nonvanishing four-dimensional curvature.

Pág. 202 (221) -

At the same time, Cassirer emphasized the philosophical relevance of Einstein's theory insofar as it presupposed a revision of the principles of measurement.

The space-time structure of general relativity is characterized by the fact that the measure of curvature depends on physical factors.

Therefore, Einstein replaced the Euclidean form of the line element with the general form:

$$ds^2 = \sum_{1}^{4} g_{\mu\nu}\, dx_\mu\, dx_\nu,$$

and adopted Riemannian geometry for the expression of the measure of curvature of space-time in its correlation with matter.

Regarding Einstein's use of Riemannian geometry, Cassirer maintained that the relations between Euclidean and non-Euclidean geometry appeared in a new light.

Lorentz transformation equations for distances and times, on the basis of which the relation between v_s and v can be calculated.

The result of this calculation is as follows:

$$\boxed{v_s = \frac{v - V}{1 - vV/c^2}}$$

Furthermore, on considering a velocity-space in which the rule for adding and subtracting velocities

is given by the above expression, one finds that the space in question is Lobachevskian (or hyperbolic).

Such a space possesses a constant negative curvature; by comparison, the curvature of Euclidean or pseudo-Euclidean is zero.[12]

[12] → Kant - Critique of Pure Reason

"Kant suddenly and completely altered the situation and ... substituted for the problem of objectivity [central to the first edition of "Critique of Pure Reason"] that of the limitation of pure reason to phenomena as the real Critical demonstrandum"

IMPORTANT:

Kant's reversal of relative space procedure would provide an intuitive representation of relativistically composite motions only if we were capable of grasping intuitively the addition of distances in Lobachevskian space.

Binocular visual space suggest that it possesses precisely a constant negative curvature.

...) the curvature of Euclidean or pseudo-Euclidean space is zero.[12]

[12]- Pág. 111(120)-

The mathematics of this result may be sketched as follows. We begin with the Lorentz transformations for distance and time:

$$x' = \frac{x - Vt}{\sqrt{1 - V^2/c^2}},$$

$$t' = \frac{t - \frac{Vx}{c^2}}{\sqrt{1 - V^2/c^2}}$$

two coordinate systems, S and S', in uniform motion V along their mutual x-x' axes; and c is the velocity of light. Consider now a particle moving

PARALLEL TO THE x-x' AXES.

obs: Nós devemos discutir este paralelismo e a velocidade constante.

A velocidade da luz como limite físico é algo indiscutível, mas eu penso que de acordo com a geometria empregada, Geometria Hiperelíptica, a velocidade da luz não será uma constante intransponível.

A Geometria apresenta aspectos ainda por serem descobertos e portanto, há novos caminhos a serem aplicados à realidade em que vivemos.

Nós podemos viajar mais rápido que a velocidade da luz sem a necessidade de dobrarmos o espaço-tempo. Portanto, não há a necessidade do emprego de grandes quantidade de energia para uma viagem no espaço profundo.

Com o emprego de uma matemática moderna e mais precisa do que temos hoje, aliado à uma geometria hiperelíptica contestadora dos atuais limites físicos criados pelo próprio homem, nós poderemos nos deslocar de forma mais rápida e econômica sem a necessidade de

emprego massivo de energia para gerar campos eletromagnéticos que distorcem o espaço-tempo. Seria como utilizar o sistema de enrolamento de corrente-alternada aliado ao princípio da indução elétrica de Nikola Tesla para tentar torcer o espaço-tempo.

Nós temos também o problema do aumento da velocidade que gera também um "aumento" no peso da espaçonave, necessitando assim, mais energia para aumentar a velocidade, exigindo grandes quantidades de energia. Diante deste problema, nós devemos estar atentos ao principal problema para se poder acelerar uma espaçonave no espaço, que é a transmissão de energia de forma eficiente.

Vejamos, não basta produzir energia em grandes quantidades, como aquelas produzidas pela fusão nuclear e que por sinal, não será resolvida de forma eficiente e produtiva sem uma nova matemática e geometria.

Partindo-se do pressuposto que tal tecnologia já estivesse disponível para a humanidade e que o homem estivesse tão desenvolvido que pudesse miniaturizar os reatores de fusão nuclear

a ponto de serem utilizados em espaçonaves, nós teríamos a questão da transmissão desta energia de forma eficiente e direta sem a perda de energia entre a produção e o efetivo emprego pela espaçonave.

Com a geometria hiperelíptica, nós poderemos "cortar caminho" entre um ponto e outro ponto, usando novos caminhos sem a necessidade de mecanismos mirabolantes e exóticos, caros e muitas vezes, ineficiente.

Com a nova matemática, nós teremos:

eficácia, eficiência e efetividade

no emprego desta nova matemática aplicada à geometria hiperelíptica, que abrirá novos caminhos da física de modo que possamos viajar grandes distâncias sem o emprego de grandes quantidades de energia.

Nova matemática, nova geometria = novos caminhos.

Return : Pág. 111 (120)

If we designate the velocity of the particle in S by v and in S' by v', then v and v' will be related as follows:

$$v' = \frac{dx'}{dt'} = \frac{\frac{dx}{dt} - V}{1 - \frac{V}{c^2}\frac{dx'}{dt}}$$

$$v' = \frac{v - V}{1 - \frac{Vv}{c^2}}$$

Pág. 112 (121) →

Suppose now that we evaluate dv'^2, the squared increment of v', by substituting

$V = v + dv$ in the formula for v'^2.

The resuet is as follows:

$$dv'^2 = \frac{dv^2}{\left(1 - \frac{v^2}{c^2}\right)^2},$$

where the term $v\,dv/c^2$ in the denominator has been ignored as very small compared with

v^2/c^2. Since it can be shown that an identical formula holds for dv^2 as a function of dv'^2 and v', it follows that dv'^2 is invariant (like the interval defined for space-time), and hence may be thought of as defining a metric for velocity-space.

Recalling the well-known expression for "distance" in Riemannian space:

$$ds^2 = \frac{\sum_{i=1}^{n} dx_i^2}{\left[1 + \frac{K}{4}\sum_{i=1}^{n} x_i^2\right]^2},$$

we see that K, the measure of curvature, is $-4/c^2$ in velocity-space, thereby confirming the fact that the curvature is constant and negative.

Of course, we have been considering only the special case in which the velocities v and V are PARALLEL, (?)

so that the resulting velocity-space is one-dimensional.
For the general case, see Fock (1964, pp. 45-53).

Pág. 01(15) - Introduction

Esta introdução nos fornece uma visão geral sobre o espaço-tempo, mas apresenta inconsistências incompatíveis com uma nova matemática e geometria →

geometria hiperelíptica ou Musichiana

Vejamos (see):

From the geometrical point of view the theory of space and time naturally divides into the

theory of uniform space (Galilean),

and the

theory of non-uniform space (Riemannian and Einsteinian).

obs: Now,

$$\boxed{\text{theory of non-uniforme space hiperelliptic Riemannian}}$$

Galilean space is of maximal uniformity. This means that in it:

a) All points in space and instants in time are equivalent;

b) All directions are equivalent, and

c) All inertial systems, moving uniformly and in a straight line relative to one another, are equivalent

(Galilean principle of relativity)

The uniformity of space and time manifests itself in the existence of a group of transformations which leave

INVARIANT THE FOUR-DIMENSIONAL DISTANCE

or

interval between two points.

The expression for this interval plays an important part in the theory of space and time because its form is directly related to the form taken by the

BASIC LAWS OF PHYSICS,

the law of motion of a free mass-point

and the

law of propagation in free space of the front of a light wave.

The indications (a), (b), and (c) of the uniformity of Galilean space are related to the following transformations:

→

a) To the equivalence of all points and instants corresponds the transformation of displacing the origin of the spatial coordinates and of time; the transformation involves four parameters, namely, the three space coordinates and the time coordinate of the origin.

b) To the equivalence of all directions corresponds the transformation of rotating the spatial coordinate axes; this involves three parameters, the three angles of rotation.

c) To the equivalence of inertial frames corresponds a change from one frame of reference to another moving uniformly in a

straight line (?)

with respect to the first. This transformation involves three parameters, the three components of relative velocity.

The most general transformation involves ten parameters.
This is the Lorentz transformation.

It is well known that in a space of n dimensions the group of transformations which leave invariant the expression for the squared distance between infinitely near points, can contain at most

$\boxed{\frac{1}{2} n(n+1)}$ parameters.

If there is a group involving all $\frac{1}{2} n(n+1)$ parameters then the space is of maximal uniformity; it may be a space of constant curvature, or, if the curvature vanishes, a Euclidean or pseudo-Euclidean space.

Pág. 02(16)-

In the case of space-time the number of dimensions is four and therefore the greatest possible number of parameters is ten. This is also the number of parameters in the Lorentz transformation, so that

Galilean space, to which the transformation relates, is indeed of maximal uniformity.

It is customary to call the theory based on the Lorentz transformation the

Special Theory of Relativity.

More precisely, the subject of that theory is the formulation of physical laws in accordance with the properties of

Galilean space.

The creator of the theory of relativity was

Albert Einstein (1879-1955).

Poincaré and Lorentz should be considered his predecessors.

Interesante!!!

Universal gravitation does not fit into the framework of uniform Galilean space.

The deepest reason for this fact was given by Einstein.

→

It is that not only the inertial mass, but also the gravitational mass of a body depends on its energy.

...

Mathematically this meant abandoning Euclidean, or rather pseudo-Euclidean, geometry in favour of the geometry of Riemann. The modern theory of gravitation was also "created" by Einstein.

According to gravitational theory there exists in the infinitely small a uniformity like the one expressed by Lorentz transformation.

Interessante !!!

That this is so is connected with the fact that in the vicinity of a given point of space the gravitational field can be imitated by a field of acceleration (the so-called Principle of Equivalence).

The physical basis of this is the law already known to Galileo that in the absence of a resistive medium all bodies fall equally fast, or, more accurately, with equal acceleration.

The law of Galileo can be stated

in generalized form as the law of the equality of inertial and gravitational mass.

It should be stressed that this fundamental law is of a general character whereas (en quanto que) the principle of equivalence is strictly local.

The law of the equality of inertial and gravitational mass applies to the extent to which it is possible to define inertial and gravitational properties of mass as attributes of a particular body, independently of the positions and motions of other bodies.

(Such independence exists in Newton's theory of gravitation, but does not necessarily hold in generalizations of that theory).

Pag. 150 (164) — 43.

The Curvature Tensor.

Pag. 155 (169) — Finally, the curvature tensor of a two-dimensional surface ($n=2$) has only one component - the Gaussian curvature.

Pág. 176 (190) -

We first discuss these equations in the general case that the fourth order curvature term is not necessarily zero.

...

$$R_{\mu\nu,\alpha\beta} = K(g_{\nu\alpha} g_{\mu\beta} - g_{\mu\alpha} g_{\nu\beta}) \quad (49.12)$$

where K is a constant.

A space in which the curvature tensor has the form (49.12) is called a space of constant curvature; it is a four-dimensional generalization of Lobachevsky space.

The constant K is called the constant of curvature.

...

We are interested in the case

$$R_{\mu\nu,\alpha\beta} = 0 \quad (49.13)$$

which is obtained from (49.12) by taking $K = 0$.

(For this reason a space for which $R_{\mu\nu,\alpha\beta} = 0$ is called a space of zero curvature, or a flat space).

Pág. 204 (218) →

The four-dimensional Christoffel symbols and the curvature tensor can be expressed in terms of the corresponding three-dimensional quantities.

Pág. 211 (225)

: owing (devido) to the symmetry properties of the fourth rank curvature tensor

these terms vanish if the coordinate system is orthogonal.

Pág. 257 (271) -

Outside the masses U^* satisfies d'Alembert's equation with Euclidean coefficients.

This could be expected in view of the form (68.17) of the Lagrangian.

At the end of Section 67 we found an approximate expression for the scalar of curvature R

in terms of the function

$$f = \sqrt[4]{\left(\frac{-g}{c^2}\right)} \qquad (68.31)$$

which is proportional to the fourth root of the absolute value of the determinant g.

Pág. 382(396) -

The spatial part of ds^2, which corresponds to a fixed value of the universal time T (and therefore also to fixed τ) is equal to

$$dl^2 = \tau^2 \left(1 - \frac{\alpha}{\tau}\right)^4 d\sigma^2 \qquad (94.56)$$

This describes a Lobachevsky space of constant negative curvature.

It's volume is infinite.

Pág. 422(437) - Appendix D.

The Transformation of the Einstein Tensor

(a) the Transformation of the Second Rank Curvature Tensor

Pág. 425 (439) –

(b) Transformation of the Invariant

We now form the invariant of the curvature tensor:

$$R = g_{\mu\nu} R^{\mu\nu} \qquad (D.38)$$

Pág. 174 (182) –

IV. Homogeneity and Isotropy

Poincaré is careful to remind us that representative spaces are neither homogeneous nor isotropic. →

Interessante:

...; as Kant remarked against Leibniz, our intuition allows us not only to distinguish between left and right, but also to determine what in the world is left, and what is right.

Now, our axioms do not completely determine space.

The description of space as being illimited, continuous, three dimensional, homogeneous and isotropic indeed fits (real se encaixa) all spaces with constant curvatures, that is,

Pág. 175 (183)

, it fits as well as the Euclidian space with curvature zero the Bolyai-Lobatschewskyan space with constant negative curvature or the Riemannian space with constant positive curvature.[5]

[5] - Pág. 177 (185) →

Klein (1925, II, p. 199) reminds us that in every non-Euclidean geometry (of constant curvature)

there is a six-dimensional group of "motions", which leave angles and distances invariant.

We come to the Euclidean system when we distinguish, among the motions, the subgroup of parallel displacements; such subgroups do not exist in non-Euclidean geometries.

Pág. 221 (229) –

Using such a nonstandard measuring procedure to instantiate the hemispherical fundamental form, the occupants of the plane would find a value of

$$\boxed{1/r \text{ for the Gaussian Curvature}},$$

and would conclude that the geometry of their "world" was elliptic.

Pág. 270 (278) – Grünbaum charges the advocates of geometrodynamics, Clifford and Wheeler in particular, with inconsistency.

Since these men have maintained that matter reduces to curved space, they must also have thought, according to Grünbaum, that

curvature is an intrinsic property of space.

Pág. 272 (280)

Glymour's conflation

Let me refer to the claim that space is both intrinsically curved and yet devoid (desprovido) of any intrinsic metric as "MUC" to convey its assertion of the feasibility of the Metrical Unsupportedness of Intrinsic Curvature.

And let me call the charge that MUC is inconsistent "The Inconsistency Charge".

Pág. 273 (281) →

Gaussian curvature K – the vanishing curvature K of that two-space fails to determine a Riemannian metric or metric tensor

which is unique up to a choice of unit.

Thus, I had denied the uniqueness claim GRUM with respect to the Riemannian (Gaussian) curvature of two-space.

Pag. 282 (290) –

Glymour (1973)

1) Space-time has intrinsically, certain curvature properties;

2) Space-time does not have, intrinsically, a metric

and

3) Material bodies reduces to curved space-time [Footnote 8].

Pag. 286 (294)

Riemannian curvature K (equation)

K_η at a point P of a Riemann space with respect to the orientation N determined by two linearly independent

contravariant vectors A^i and B^i is given by

$$K_\eta = \frac{R_{abcd} A^a B^b A^c B^d}{(g_{ac} g_{bd} - g_{ad} g_{bc}) A^a B^b A^c B^d}.$$

But the (0,4) curvature tensor in the numerator and the (0,2) metric tensor in the denominator each has dimension L^2.

Pág. 292 (300) –

Turning to Wheeler we find the following statement by him in Foreword to his book Geometrodynamic (1962b):

The sources of the curvature of space-time are conceived differently in geometrodynamics and in usual relativity theory.

...

Misner in 1956 (III), gave a way to think of electromagnetism as a property of curved empty space [p. xi].

Pág. 465 (466) — 5.

Geometría sobre la superficie de curvatura constante

§227. Nuestro objeto es hallar, si es posible, en el espacio euclidiano una superficie, para cada punto de la cual exista un entorno isométrico respecto a cierto dominio del plano de Lobachevski:

Obs: Parágrafo anterior (return)

Si formulamos precisamente en términos de la isometría la pregunta formulada, de pronto puede verse que la misma conduce a dos problemas distintos:

1) Hállese una superficie, para cada punto de la cual exista un entorno isométrico respecto a cierto dominio del plano de Lobachevski

En cuanto a una superficie tal, aún no puede decirse que su geometría en total sea idéntica a la del plano de Lobachevski.

(Así, por ejemplo, cada punto de un cilindro circular tiene un entorno que puede desarrollarse y superponerse sobre cierto sector del plano euclidiano. Sin embargo, la geometría del cilindro circular, en total, difiere substancialmente de la geometría de un plano)

Diremos que sobre una superficie que satisfaga las condiciones del problema, la geometría de Lobachevski se realiza "localmente".

2) Hállese una superficie que admita su aplicación isométrica sobre todo el plano de Lobachevski.

La geometría interior de tal superficie debe representar la

realización de la planimetría no euclidiana dentro del espacio de Euclides.

De la solución positiva del segundo problema se deduciría directamente la consistencia lógica del sistema no euclidiano bidimensional. Precisamente, tal objetivo lo perseguía Beltrami al que se debe, como se dijo más arriba, el planteo de estos problemas. Pero Beltrami dejó resuelto sólo el primero.

En lo que respecta al segundo, según se supo más tarde, éste no tiene solución.

A saber, D. Hilbert demostró que en el espacio de Euclides no existe una superficie que tenga la propiedad requerida.*

recta u.

Fig. 163 b → También es fácil comprender que en los puntos no singulares la tractriz tiene convexidad hacia la asíntota.

La superficie formada por el giro de la tractriz alrededor de la asíntota se llama (llama) seudoesfera (fig. 163 b)

curvature (see)

Fig. 163 b

Pág. 473 (474)

$$K = -\frac{1}{a^2}$$

Con esto mismo queda demostrado que en todos los puntos la Seudoesfera tiene una misma curvatura negativa igual a

$-\frac{1}{a^2}$, donde a es un parámetro de la tractriz, mediante cuya revolución se ha formado la seudoesfera dada.

Interessante!!!

Evidentemente, existe una seudoesfera con cualquier curvatura negativa dada con anterioridad.

...

entorno de cualquier punto de la seudoesfera la forma métrica tiene el aspecto siguiente en las coordenadas semigeodésicas (con la geodésica básica)

$$ds^2 = ch^2(\sqrt{-K}\,v)\,du^2 + dv^2$$

(§227, fórmula (C)).

Importantísimo!!!

Deformando cierto trozo de la seudoesfera, se puede obtener infinidad de otras superficies de curvatura negativa constante.

Así pues, cualquiera que sea

$$\lambda' \ (-\infty < K < +\infty),$$

en el espacio de Euclides, existe una superficie de curvatura constante K.

Ser:

En lo que se refiere a la solución del

PROBLEMA DE BELTRAMI,

llegamos a la conclusión que sigue: si en el espacio euclidiano existen superficies, sobre las cuales se realiza localmente

la geometría de Lobachevski, entonces una de tales superficies será o bien <u>esfera</u>, o bien <u>plano</u>, o bien <u>seudoesfera</u>.

Pág. 473 (474) –

Al final del §224 encontramos <u>la expresión de la forma métrica del plano de Lobachevski</u>

en las primeras coordenadas ξ, η:

$$ds^2 = ch^2 \frac{\eta}{R} d\xi^2 + d\eta^2 \quad (**)$$

...

Vemos que (**) coincide precisamente con la última de las tres formas

<u>obs</u>: $ds^2 = ch^2(\sqrt{-K}\, v)\, du^2 + dv^2$.

<u>Portanto</u>: para $\frac{1}{R} = \sqrt{-K}$.

<u>Important</u>:

De aquí sigue el <u>Teorema de Beltrami</u>

En el entorno de cada punto de una <u>seudoesfera</u> tiene lugar la geometría de <u>Lobachevski</u>.

Pág. 475 (476) — 6.

Deducción de las relaciones métricas fundamentales en la geometría de Lobachevski:

$$x^2 + y^2 < 1 \qquad (*)$$

Consideremos un plano euclidiano Σ con un sistema de coordenadas rectangulares cartesianas (x, y).

La relación $(*)$ determina un dominio interior de un círculo unitario

K_1 sobre Σ.

<u>Interesante!!!</u>

Comparemos un punto del plano Σ (situado dentro ~~de~~ del círculo K_1), cuyas coordenadas cartesianas son los números x, y, con un punto arbitrario

del plano de Lobachevski, cuyas coordenadas cartesianas son los mismos x, y.

...

Con este mismo establecemos cierta aplicación especial de todo el plano de Lobachevski sobre el interior del círculo K_1; para esta aplicación serán

<u>imágenes de las rectas de Lobachevski</u>

<u>las cuerdas del círculo K_1</u>

(desde luego, con los extremos excluidos)

Pág. 476 (477)

Pág. 399 (400) – §5.

Reducing to canonical form the general equation of a quadric hypersurface in Euclidean Space.

1. Quadric hypersurfaces are divided into several classes for which we obtain distinct elementary, or canonical, forms of the equations.

2. In the theoretical exposition we will not strive to save on operations and will begin with a rotation of the coordinate system.
   In practical computations, if the surface is central, then as a first step it is best to carry the origin to the centre.

Pág. 402 (403)

§6. Classification of quadric hypersurfaces in Euclidean space.

Pág. 405 (406) - ellipse

Fig. 78 and 79.

⇒ A profundar pesquisa.

The quantities a_i are called the semiaxes of the ellipsoid ($a_i > 0$),

it is easy to verify that the ellipsoid is located in a parallelepiped defined by the inequalities

$$|x_i| \leq a_i,$$

$$i = 1, \dots, n.$$

(For $n=3$ see Fig. 78, for $n=2$ see Fig. 79).

Note that a k-dimensional ellipsoid for $k=1$ is an ellipse (Fig. 79);

for $k=0$ it is a pair of points $x_1 = \pm a_1$ (Fig. 80)

Pág. 406 (407) - Fig. 81

Hyperboloids

Obs: Estudar esta curvatura em relação ao meu posicionamento geométrico (geometria hiperbólica)

See: Fig. 82 and 83.

1) For $n=2$, equation (4) takes the form

$$\frac{x_1^2}{a_1^2} - \frac{x_2^2}{b_1^2} = 1 \text{ and}$$

specifies a hyperbola (Fig. 81).

2) For $n=3$ there are two possibilities: a hyperboloid of two sheets (Fig. 82):

$$\frac{x_1^2}{a_1^2} - \frac{x_2^2}{b_1^2} - \frac{x_3^2}{b_2^2} = 1 \quad (5)$$

and a hyperboloid of one sheet (Fig. 83):

$$\frac{x_1^2}{a_1^2} + \frac{x_2^2}{a_2^2} - \frac{x_3^2}{b_1^2} = 1$$

(3) $n = 4$. Here we have to consider three cases:

a) the hyperboloid of two sheets

$$\frac{x_1^2}{a_1^2} - \frac{x_2^2}{b_1^2} - \frac{x_3^2}{b_2^2} - \frac{x_4^2}{b_3^2} = 1, \quad (6)$$

b) the equation

$$\frac{x_1^2}{a_1^2} + \frac{x_2^2}{a_1^2} - \frac{x_3^2}{b_1^2} - \frac{x_4^2}{b_2^2} = 1$$

c) A hyperboloid similar to the one sheeted hyperboloid:

$$\frac{x_1^2}{a_1^2} + \frac{x_2^2}{a_2^2} + \frac{x_3^2}{a_3^2} - \frac{x_4^2}{b_1^2} = 1.$$

<u>Obs.</u>: With all hyperplanes $x_4 =$ constant it intersects along two-dimensional ellipsoids whose semiaxes increase with increasing $|x_4|$;

with the remaining hyperplanes $x_i =$ constant it intersects in hyperboloids (one-sheeted or two-sheeted) that into

<u>CONES</u>

if $x_i = \pm a_i$.

Pág. 415 (416) – §9.

The intersection of a <u>straight lines</u> with a quadric hypersurface asymptotic directions.

Pág. 416(417) →

In order to see these points, consider a circle $x^2+y^2=1$, on a two-dimensional complex plane.

For a model of a two-dimensional complex plane we take four-dimensional real space (see Section 11, Chapter I).

Fig. 85

Set

$$x = u + i\xi, \quad y = v + i\eta \qquad (4)$$

Putting these expressions into the equation of the circle and separating the real and imaginary parts, we get

$$\left.\begin{aligned} u^2+v^2-\xi^2-\eta^2 &= 1, \\ u\xi + v\eta &= 0 \end{aligned}\right\} \qquad (5)$$

System (5) shows that the circle
$x^2+y^2=1$,
considered on the two-dimensional complex plane (4), is depicted (representado) in the

four-dimensional space of the variables

(u, v, ξ, η)

as the intersection of a

hyperboloid and a cone.

The straight line

$x=-2$ is depicted in the space of variables

(u, v, ξ, η) as a two-dimensional plane:

$$u=-2, \quad \xi=0 \qquad (6)$$

Consider in four-dimensional space the three-dimensional subspace $\xi=0$.

The plane (6) is completely contained in it, while the circle (5) intersects this subspace in the figure

$$\left.\begin{aligned} u^2+v^2-\eta^2 &= 1, \\ \eta v &= 0 \end{aligned}\right\} \quad (7)$$

consisting of the ordinary circle

$$u^2+v^2=1, \quad \eta=0$$

(it is precisely this circle that we see on the real Euclidean plane) and of the hyperbola

$$u^2-\eta^2=1, \quad v=0$$

Pag. 417 (418) →

(Fig. 86) the plane (6) and the figure (7) intersect in the same points

$$u=-2, \quad v=0, \quad \eta=\pm\sqrt{3}$$

that have just been under discussion.

Pág. 418 (419)

These straight lines may be called <u>asymptotic lines</u>, and the cone an <u>asymptotic cone</u>.

<u>Fig. 88</u>

Instances are the asymptotic cones of hyperboloids in <u>three dimensional space</u> (Fig. 88) and the asymptotes of a hyperbola for $n = 2$.

Pág. 420 (421) →

2. Hyperplane (5) is called the

<u>diametral hyperplane conjugate</u>

to the direction l with respect to the given <u>hypersurface</u>.

It bisects every <u>chord parallel</u> to l.

3. The numbers

$N_1, \dots, N_n$ form the coordinates of a vector $N = \{N_1, \dots, N_n\}$.

Fig. 89.

We assume the coordinates in space to be orthonormal.

Then vector N is orthogonal to the diametral hyperplane (5), that is to say, it is its normal vector.

The relations

$$N_i = \sum a_{ik} l_k \quad (i = 1, \dots, n)$$

may be regarded as the linear transformation

$$N = A l$$

which carries vector l into vector N (Fig. 89)

This is precisely the self-adjoint linear transformation that engaged us when we investigated the general equation of a quadric hypersurface.

Search: curvature

Pág. 140 (143) - Chapter IX
Curvature and Torsion of Curve

1. Length of a curve

Let an elementary curve be given by equations

$$x = x(t),\ y = y(t),\ z = z(t).$$

Pág. 142(145) – 3. Curvature

Let P be an arbitrary point of a regular curve γ, and Q its point near to P.

Denote by $\Delta\theta$ the angle between the tangents at P and Q, and by $|\Delta s|$ the length of the arc PQ (Fig. 92).

Fig. 92

The limit of the ratio $\Delta\theta / |\Delta s|$ as $Q \to P$ is called the curvature of γ at P.

A regular (twice continuously differentiable) curve has certain curvature k_1 at each point.

If $r = r(s)$

is the <u>natural parametrization</u> of the curve, then

$$K_1 = |r''(s)|.$$

Let two points P and Q be associated with values s and $s + \Delta s$ of the parameters.

The angle $\Delta\theta$ equals that between the unit tangent vectors $\tau(s) = r'(s)$ and $\tau(s+\Delta s) = r'(s+\Delta s)$.

Fig. 93

Since $\tau(s)$ and $\tau(s+\Delta s)$ are unit, and make the angle $\Delta\theta$,

$$|\tau(s+\Delta s) - \tau(s)| = 2 \sin \frac{\Delta\theta}{2}$$

(Fig. 93) $\longrightarrow$

Hence,

$$\frac{|\tau(s+\Delta s)-\tau(s)|}{\Delta s} = \frac{2\sin\frac{\Delta\theta}{2}}{\Delta s} =$$

$$\frac{\sin\frac{\Delta\theta}{2}}{\frac{\Delta\theta}{2}} = \frac{\Delta\theta}{|\Delta s|}.$$

Noticing that $\Delta\theta \to 0$ as $|\Delta s| \to 0$ by the continuity of $\tau(s)$ and passing to the limit, we obtain

$$\underline{|r''(s)| = k_1}$$ QED.

Pág. 147 (150)

thus, a curve with zero torsion at each point is plane

5. Frenet Formulas

three half-lines emanating from a point on the curve, and with the directions of three vectors τ, ν and β, are the edges of <u>a trihedral angle</u> called a <u>moving ~~tri~~ trihedral.</u>

Express the derivates of τ, ν and β with respect to the arc of the curve in terms of τ, ν and β themselves.

We have

$$\tau' = r'' = k_1 \nu.$$

To obtain β', we recall that it is parallel to ν, and $\beta'\nu = k_2$.

Hence,

$$\beta' = k_2 \nu.$$

Finally,

$$\nu' = (\beta \wedge \tau)' = \beta' \wedge \tau + \beta \wedge \tau'$$

$$= k_2 \nu \wedge \tau + k_1 \beta \wedge \nu =$$

$$= -(k_1 \tau + k_2 \beta).$$

The formulas

$$\tau' = k_1 \nu,$$

$$\nu' = -k_1 \tau - k_2 \beta,$$

$$\beta' = k_2 \nu$$

are called the Frenet Formulas.

The curvature and torsion of a curve are functions of arc lenght s

along the curve.
the equations

$$K_1 = \varphi(s), \quad K_2 = \psi(s).$$

specifying the curvature and torsion of the curve of functions of arc length s are called the <u>natural equations of curve</u>.

Pág. 161 (164) – Chapter <u>XI</u>

Surface Curvature

1. Surface Linear Element

the quadratic form

$$ds^2 = r_u^2\, du^2 + 2 r_u r_v\, du\, dv + r_v^2\, dv^2$$

is called <u>the first fundamental form</u>, or <u>surface linear element</u>.

Pág. 165 (168)

the relation (**) between <u>curvature</u> on a surface and <u>normal curvature</u> is the subject matter of the <u>Meusnier theorem</u>.

Pág. 168 (171) – 6.

Lines of Curvature.

The principal directions of an surface have been defined by us as those of the Dupin indicatrix axes.

Pág. 170 (173) – 7.

Mean and Gaussian Curvature of a Surface.

The mean curvature of a surface is half the sum of the principal curvatures.

The total, or Gaussian curvature of a surface is the product of the principal curvatures.

At an elliptic point the principal curvatures have like signs; therefore, the Gaussian curvature is positive.

At a hiperbolic point the principal curvatures have unlike signs; therefore, the Gaussian curvature is negative.

→

At a parabolic or planar point, the Gaussian curvature is zero.

IMPORTANT!!!

Estudar a curvatura de Gauss, pois haverá uma alteração dos cálculos.

A curvatura será alterada pela deformação do espaço causada pelas três forças fundamentais da física. (bending light)

Pág. 171 (174) →

According to F. Gauss, the total curvature of the surface at P is the limit of the ratio of the area of g to that of g as g is contracted to P.

We show that this definition leads to the same expression, i.e., the principal curvature product. For simplicity, we confine ourselves to the case of an elliptic point P.

Attention!!!

→

Pág. 172 (175) → 8.

Pág. 175 (178) → Chapter XII

1. Gaussian Curvature as an Object of the Intrinsic Geometry of Surfaces.

Intrinsic geometry of a surface

which studies the properties of the surface and its figures in relation

only to the lenght of curves

Pág. 177 (180) →

Gaussian curvature is

$$K = -\frac{1}{\sqrt{G}}(\sqrt{G})_{uu},$$

to see which, it suffices to make

use of the above (Gauss) formula.

Pág. 178(181) – 2.

Geodesic lines on a surface

Obs: De acordo com a nova geometria hiperelíptica, as linhas geodésicas apresentarão um novo delineamento, os cálculos serão alterados em uma nova configuração matemática.

Pág. 180(183) – 4.

Surfaces of Constant Gaussian Curvature.

Obs: Será alterada também !!!

Let Φ be a surface of constant Gaussian curvature K, and P a point on it.

Draw an arbitrary geodesic $\bar{\gamma}$ through P, and introduce a semi-geodesic parametrization in its neighbourhood by taking the geodesic orthogonal to $\bar{\gamma}$ as the family of u-curves.

The surface linear element then assumes the form

→

$$ds^2 = du^2 + G\,dv^2.$$

We take arc length along $\bar{\gamma}$ as the parameter v.
Therefore, $G(0, v) = 1$ along it, i.e., when $u = 0$.

We show that then $G_u = 0$ on $\bar{\gamma}$.
Since $\bar{\gamma}$ is a geodesic,

$$(r_{vv}\, r_v\, n) = 0.$$

We obtain

$$r_{vv} = \alpha r_u + \beta r_v + \gamma n. \quad (*)$$

Extended Theories of Gravity

Pag. 07 → In other words, the distribution of matter has to influence point by point the local curvature of the space-time structure.

The theory, eventually formulated by Einstein in 1915, was strongly based on three assumptions that the Physics of Gravitation has to satisfy.

The "Principle of Relativity", that requires all frames to be good frames for Physics, so that no preferred inertial frame should be chosen a priori (if any exist).

The "Principle of Equivalence", that amounts to require inertial effects to be locally indistinguishable from gravitational effects (in a sense, the equivalence between the inertial and the gravitational mass).

the "Principle of General Covariance", that requires field equations to be "generally covariant"
(today, we would better say to be invariant under the action of the group of all space-time diffeomorphisms).[511]

[511] → E. Schrödinger
Space-Time Structure,
Cambridge Univ. Press
(1960)

And – on the top of these three principles – the requirement that causality has to be preserved (the "Principle of Causality"
i.e. that each point of space-time should admit a universally valid notion of past, present and future).

Let us also recall that the older Newtonian theory of space-time and gravitation, that ...
(continuar)

20231205185300 SHH.

20231206080000

20231127-Extended-Theories-of-Gravity.pdf

Pag. 7 → Let us also recall that older Newtonian theory of space-time and gravitation, that Einstein wanted to reproduce at least in the limit of weak gravitational forces

(what is called today the "post-Newtonian approximation"), required space and time to be absolute entities, particles moving in a preferred inertial frame following curved trajectories, the curvature of which (e.g. the acceleration) had to be determined as a function of the sources (i.e. the "forces").

On these bases, Einstein was led to postulate that the gravitational forces have to be expressed by the

curvature of a metric tensor field

$$ds^2 = g_{\mu\nu}\, dx^\mu dx^\nu$$

on a four-dimensional space-time manifold, having the same signature of

Minkowski metric,

e.g, the so-called "Lorentzian signature", herewith (consistio) assume to be $(-, +, +, +)$.

He also postulated that space-time is curved

in itself and that its curvature is locally determined by the distribution of the sources, e.g., being

space-time a continuum,

by the four-dimensional generalization of what is

Continuum Mechanics is called the

"matter stress-energy tensor",

e.g, a rank-two (symmetric) tensor $T^{(m)}_{\mu\nu}$.

Hilbert and Einstein proved that the field equations for a metric tensor

$g_{\mu\nu}$, related to a given

distribution of matter-energy, can be achieved by starting from the Ricci curvature scalar

R which is an invariant.

...

Levi-Civita in 1919, curvature is not a

"purely metric notion"

but, rather, a notion related to the "linear connection" to which

"parallel transport" and

"covariant derivation"

Parallel Postulate

A)

B)

a || b (são paralelas?)

obs: Estudar com atenção!!!

IMPORTANT:

As linhas a, b, c, d, e passam pelo ponto P dentro do círculo.

Fazer as simulações:

a) Primeiro para observar se os mesmos ficam paralelas entre si e quais delas ficarão paralelas dentro da simulação matemática

b) Segundamente, a linha vermelha 1

tem uma menor angulação em relação a reta a (azul).

Analisar se a menor angulação favorece o paralelismo ao longo da simulação matemática.

Pág. 246 (268) → Abb 262
Abb 263

Usar para unir linhas retas e também paralelas.

Abb. 262

Straight line

Obs: De uma curva convexa, obtemos uma reta.

Abb. 263

a e b são paralelas!

Obs: Nós temos duas opções para nós obtermos as linhas paralelas

a) as linhas vermelhas interceptam as linhas pontilhadas que dividem o círculo em quatro parte.

b) as linhas vermelhas interceptam as linhas curvas como Abb. 262.

See:

Abb. 263

Neste caso, a linha vermelha intercepta a linha pontilhada.

A linha vermelha intercepta as duas curvas convexas.

1. Cyclic displacement and the relations between parallelism and curvature.

Pág. 193 (208) → 9.

Application to surfaces. Gaussian curvature of a V_2.

In considering the particular case of a V_2, i.e. an ordinary surface, the directions u, v must

of course be contained in the section (the only one there is) defined by

ξ, η.

...

$$\frac{Da}{DI} = -K \qquad (29)$$

Pag. 194 (209)

<u>Return:</u>

From this it will be seen that the function of position K defined by (28)

$$\hookrightarrow \frac{(12, 12)}{a} = K, \qquad (28)$$

<u>is an invariant</u>;

it depends on the coefficients a_{ik} and their first and second derivatives, and is identical with the quantity which in the theory of Surface ~~is~~ is know as the

<u>TOTAL or GAUSSIAN</u>,

curvature (the product of the curvatures

of the principal sections).[1]

[1] → See also below, Chapter IX, § 5.

Obs.: Pag. 242 (257)

Chapter IX

Differential Quadratic Forms of Class Zero and Class One.

Pag. 258 (273) → 5.

Hyperspherical representation and curvature of a hypersurface.

Take any hypersurface V_n, and consider it as immersed in a Euclidean space S_{n+1}; and consider also a hypersphere of unit radius and centre the origin.[2]

[2] → that is to say, as explained in § 7 of the preceding chapter a hypersurface Ω_n whose equation in Cartesian co-ordinates is →

$$\sum_{1}^{n+1} {}_{\nu}\, y_{\nu}^{2} = 1.$$

Return: Pág. 194(209) →

... Gaussian curvature (the product of the curvatures of the principal sections).[1]

The equation (29) can be put in a more instructive form if we introduce the

ANGLE OF PARALLELISM

ϵ, i.e.

the angle between u and $u+Du$ (or between u and its parallel obtained by displacement round the circuit), measured in the sense in which the circuit is described.

We can also say that ϵ is the angle through which u has been rotated as a result of the cyclic displacement.

Pág. 195(210) → It is obvious that ϵ has the same absolute

values as Da, but we shall see that as regards sign the precise relation is

$$\epsilon = -Da.$$

IMPORTANT:

Fig. 3

Obs:

A deformação com a nova geometria hyperelíptica não alteram esses valores.
(ângulos, curvatura).

To show this we need only remember the convention adopted above (§7)

Pág. 186 (201) – 7
Cyclic displacement round any infinitesimal circuit

Cont.
(§7) that the circuit is to be described in the positive sense with respect to the co-ordinate lines ξ_1, ξ_2, or from the vector ξ to the vector η,

As ξ an η now coincide with u and v the sense in which the circuit is described is from u to v

(through the convex angle)

Obs: O Valor será alterado!!!

Accordingly (see fig. 3) if $Da > 0$, $u + Du$ is outside the convex angle $\widehat{uv}$, and is therefore reached from u by moving in the negative sense ($\epsilon < 0$), and vice-versa.

We can therefore write (29) in the form

$$\frac{\epsilon}{DI} = K \qquad (29')$$

which gives the following important interpretation of the curvature K:

IMPORTANT!!!

→

$\boxed{\text{K is the ratio of the angle of parallelism}}$

(taken with its proper sign in relation to the sense of describing the circuit)
to the area of the circuit.

In the case of a Euclidean V_2, <u>Riemann's symbol</u> is zero (cf. §4) and therefore $K=0$.

This can also be deduced from the geometrically obvious fact (already used in §2) that the

<u>parallel displacement</u>
<u>is</u>
<u>integrable</u>

(i.e. that the result does not depend on the <u>curve of</u> displacement).

Pág. 195 (210). — cont.

10. Riemannian curvature of a V_n.

If instead of a surface we consider any V_n whatever, the notion of curvature becomes less simple.

If P is a fixed point of the V_n, then with every section through P determined by two arbitrary directions ξ, η drawn from P we can associate an invariant K, which is called the

RIEMANNIAN CURVATURE of the V_n at P

with respect to the section considered.

Pag. 201 (216) → 12.

Curvature of a manifold of three dimensions around a point. Principal directions and invariantes.

Consider in a V_3 a generic section or facet, f, defined by two directions (vectors) u, v, whose parameters are

$$u^i, v^i \ (i = 1, 2, 3),$$

issuing from the same point P. Let w be their vector product

(Chapter VI, § 8), the moments of which are

$$w_v = \sum_{1}^{3}{}_{ij}\, \varepsilon'_{vij}\, u^i v^j \quad (v = 1, 2, 3)$$

(39)

Corresponding to the section f in our manifold V_3, we have the Riemannian curvature K given by (31), with $n = 3$.

Obs: Chapter VI, § 8 (Pág. 156 (171).

8. Some laws of transformation G-systems. Vector product. Extension of a field.

11. Case of a V_3. The tensors a_{ik} of Ricci and G_{ik} of Einstein

... § 11) that for any V_n whatever we can construct from the Riemannian tensor the symmetrical double tensor

$$G_{ik} = \sum_1^n {}_{jh}\, a^{jh}(ij, hk), \quad (1)$$

and its linear invariant

$$G = \sum_{1}^{n}{}_{ik}\, a^{ik} G_{ik} \quad (2).$$

This definition naturally holds also for an indefinite metric: in particular therefore for the ds^2 of relativity ($n=4$), in which case the tensor under discussion is called the

Einstein tensor;

IMPORTANT: (Estudar!!!)

Pág. 400 (415).

10. Displacement of the spectral lines.

Deflection of light.

Obs: Capítulo todo!!!

Pág. 405 (420)

In other words, if the radius of curvature ρ is not infinite as for a straight line, it is at

any rate of the order of a million times the sun's radius.

It is therefore perfectly legitimate to assume that the rays are in any case only very close to the sun; in every case, therefore, the hyperbola in question will have its asymptotes

Fig. 4

OA', OT' (cf. fig. 4)

almost in one straight line.

Consider in further detail the hyperbolic ray which grazes the solar sphere at V.

Let O be the centre of the hyperbola, S the centre of the sun and therefore the focus of the given branch of the hyperbola.

IMPORTANT:

The focus of the given branch of the hyperbola.

→ estudar !!!

Pág. 405 (420) →

V will be its vertex, and, if a denotes the transverse semi-axis and

e the eccentricity,

we shall have by definition

$OV = a$, $OS = ae$,

$SV = r_0 = a(e-1)$.

We know, also from analytical geometry that if

δ represents the exterior angle between the two asymptotes

$$\sin\frac{\delta}{2} = \frac{1}{e}.$$

In the case we are considering,

δ must be very small;
hence (consequentemente), from this formula,
e is very large.

Our results will be quite sufficiently accurate if we take the size of the angle δ as equal to the arc, and consider $\frac{1}{e}$ negligible in comparison with unity. Thus, we can write

$$\delta = \frac{2}{e} = \frac{2}{e}\,\frac{1}{1-\frac{1}{e}} = \frac{2}{e-1}.$$

Using the relation $r_0 = a(e-1)$, we get finally as the measure of δ in terms of the two lengths r_0 and a

$$\delta = \frac{2a}{r_0} \qquad (46)$$

IMPORTANT:

Pág. 436 (451) → We shall

conclude this section by showing that De Sitter's space-time

not only, like Einstein's, implies that physical space

(i.e. any manifold x_0 = constant)

has constant positive curvature k,

but has itself, as a four-dimensional manifold, constant negative curvature.

$$e = (r_a - r_p)/(r_a + r_p)$$

Pág. 154 (189) - Fig. 3.4.

Diagram of an orbit showing orbital inclination or "tilt".

Pág. 156 (191) - 3.3.1

Required Orbital Injection Speed.

3.3.1.1. Circular Orbit Speed

$$V = \sqrt{\frac{g_0 R^2}{r}} \qquad (3.1)$$

where g_0 is the gravitational acceleration at the planet's surface,

R is the planet radius, and

r is the orbital radius.

<u>Obs</u>: For Earth, sea level

$g_0 = 9.80665\ m/s^2$,

$R = 6{,}378\ Km$, and

$g_0 R^2 = 398{,}924\ Km^3/s^2$.

The term $\mu = g_0 R^2$ is sometimes used as an abbreviation.

Note that the circular orbit radius r is equal to the sum of the planet radius R and the orbital height h

$$r = R + h \qquad (3,2)$$

<u>Portanto</u>: $V_{ISS} = \sqrt{\dfrac{g_0 R^2}{r}}$

ISS = 407 Km da superfície.

$$V_{ISS} = \frac{398{,}924\ Km^3/s^2}{(6{,}378 + 407)\ Km}$$

$$V_{ISS} = 7.668\ Km/s$$

using the vis viva relation

$$\frac{v^2}{2} - \frac{g_0 R^2}{r} = -\frac{g_0 R^2}{2a} \qquad (3.3)$$

Rearranging and substituting for the velocity

$$v = \sqrt{g_0 R^2 \left(\frac{2}{r} - \frac{1}{a}\right)} \qquad (3.4)$$

<u>obs</u>: It may be noted that for circular orbits, the semimajor axis a is identical to the radius r, and Eq. (3.4) reduces to Eq. (3.1).

Pág. 157 (192) –

Fig. 3.5, provide a convenient formula for the required burnout speed for a coasting transfer into a general ascending transfer orbit, as shown in Fig. 3.6.

For the orbit shown, the required injection speed is

$$V_1 = \sqrt{\frac{g_0 R^2}{r_1}\left[\frac{2(r_2 - r_1) r_2 \sin^2\theta_2}{r_2^2 \sin^2\theta_2 - r_1^2 \sin^2\theta_1}\right]} \qquad (3.5)$$

For a Hohmann transfer orbit (both injection and final orbit velocity vectors are tangent to the final orbit, or $\theta_1 = \theta_2 = 90$ degrees),

the required (Pág. 159 (194)) transfer orbit injection

$$v_1 = \sqrt{\frac{2 g_0 R^2 r_2}{r_1 (r_1 + r_2)}} \qquad (3.6)$$

A Hohmann transfer orbit between r_1 and r_2 is shown in Fig. 3.7.

Note that both of these transfer orbits require a second "kick" burn <u>at apoapsis</u> to circularize at the larger radius.

This second burn is often (but not always) supplied by the payload itself.

Foundations of Geometry
Chapter XIII
Historical Survey

1. Euclid's Elements.

Postulate 5:

It is postulate that, if a straight line falling on two straight lines make interior angles on the same side less than two right angles, the two straight lines, if produced indefinitely meet on that side on which are the angles less than the two right angles.

Pág. 188 (191) – 2.

Attempts to Prove the Fifth Postulate

Fig. 106

Certain of the above defects of the Elements have already been noticed by the ancient Greeks, due to which attempts to improve the treatment were made.

The principal goal was to reduce the Euclidean postulate and axiom system to minimum.

The natural way to solve the problem is in deducing some of the postulates and axioms from the others.

The Elements were just in this way stripped (despojado) of the fourth postulate

(where the equality of all right angles was meant).

However, all the efforts to get rid of (livrar-se) the

FIFTH POSTULATE

were of no avail (não foram úteis), though (embora) geometers have tried to do it for more than two thousand years.

The typical mistake of most of its proofs was either (ou) purposeful or accidental use of some or other statement not explicitly contained in the remaining postulates and axioms,

and not following from them.

E.g. here is the proof of Proclus.

Given $\alpha + \beta < 2d$ (Fig. 106),

prove that the straight lines g' and g'' meet at a certain point C.

Draw through the point A a straight line g''' parallel to g'.

Take a point B on g'' and drop the perpendicular to g''' from it.

Since the distance from g''' increases without limit as that between B and A grows, and the distance between g' and g''' is constant, there is a point C on g'' belonging to g'.

This is just where g' and g'' meet.

The property of parallel straight lines,

to which we have resorted in the proof, is not explicitly contained in the other postulates or axioms. Moreover, it cannot be deduced from them.

THE FIFTH POSTULATE can be proved on the basis of a great many other statements.

E.g.

i) All perpendiculars to one side of an acute angle cut its other side

ii) There exist similar triangles which are not congruent

iii) There exist triangles of arbitrarily large area.

IV) There exist triangles whose angle-sum is equal to two right angles.

V) Through a point outside a given straight line, not more than one parallel line can be drawn.

→

Though the attempts to prove the fifth postulate did not lead to the desired result, they undoubtedly played a positive part in the development of geometry, often enriching it with new interesting theorems whose proofs were not based on the fifth postulate.
One of them proved by

A. Legendre

states that the sum of the angles of any triangle is not greater than 2 no right angles.

Pág. 191 (194)

A vulnerable point in the proof of Lobachevskian geometry consistency, if it is based on the BELTRAMI interpretation is, as D. Hilbert had demonstrated, that there exists no complete EUCLIDEAN surface of constant negative curvature without singularities, and, therefore, the geometry of only part of the Lobachevsky plane can be interpreted on it.

The drawback was eliminated in the later models by H. Poincaré and F. Klein.

F. Klein interpreted hyperbolic plane geometry inside a circle in the Euclidean plane, where its chords are understood as straight lines, and motions as collineations preserving the circumference.

The proof on the basis of this interpretation that Lobachevskian geometry is consistent will be seen to be irreproachable (irreprensivel).

Pag. 202 (205) – 7.

Parallel Axiom

Two straight lines on a plane are said to be parallel if they not meet.

Axiom VI:

Through a point not in a given straight line, not more than one straight line parallel to the given passes in the plane.

It follows that the property of parallelism of straight lines is transitive.

Viz., if a straight line a is parallel to a straight line b, and b is parallel to a straight line c, then a is parallel to c.

In fact, if a and c met, then two straight lines parallel to b, viz., a and c, would pass through the point of their intersection, which is contrary to Axiom VI.

It also follows from Axiom VI, that if a straight line intersects one of two parallel straight lines, then it also intersects the other.

Obs: Não necessariamente, caso a linha reta que intercepta uma linha paralela não alcance a outra linha reta.

Se em uma simulação, esta linha tiver um comprimento determinado, esta linha pode não interceptar a outra linha reta paralela.

Cont.) In fact, let a straight line

c intersect one of two parallel straight lines a and b, say, b, but not intersect the other, i.e., a.

Then two straight lines parallel to a, viz., b and c, pass through the point where b and c meet, which is contrary to Axiom VI.

Pág. 214 (217) – 8.

Independence of the Axiom of Existence of a Line Segment of Given Length.

Pág. 215 (218) –

The axiom of existence of a line segment of given length is independent, i.e., it cannot be obtained as a corollary to the other Euclidean geometry axioms.

Pág. 218 (221) – 10.

Lobachevskian Geometry.

We have proved that the PARALLEL AXIOM does not depend on the other

Euclidean geometry axioms.

It follows that the former can be replaced by its negation in the Euclidean geometry axiom system.

as transversals to be sides of PQR, prove that the equality

$$\frac{\overrightarrow{SQ}}{\overrightarrow{SR}} \cdot \frac{\overrightarrow{TR}}{\overrightarrow{TP}} \cdot \frac{\overrightarrow{UP}}{\overrightarrow{UQ}} = 1$$

holds and conclude (the most general version of Pascal's theorem is Theorem VI - 4.4).

IMPORTANT:

Pág. 208 (214) - 4.

The cross-ratio of four points an a conic and Pascal's theorem.

Pág. 209 (215) → Fig. 16

Corollary 4.3.

Let $\mathcal{C}$ be a proper conic with nonempty image and let $m_1, \dots, m_4$ be four points of $\mathcal{C}$.

The cross-ratio

$[mm_1, mm_2, mm_3, mm_4]$

does not depend on the choice of the point m on $\mathcal{C}$.

The cross-ratio is called the cross-ratio of the four points $m_1, \dots, m_4$ on the conic $\mathcal{C}$.

Pág. 209 (215) →

We are now going to prove <u>Pascal's theorem</u>, special cases of which we have already encountered (see Exercise III.51).

Pascal has proved his theorem in a circle (the general case of conics being a consequence of the special case of circles) probably using

<u>Menelaüs' theorem</u>

(Exercise I.37)

Pág. 38 (44) →

Exercise I.37 (Menelaus' theorem)

Let ABC be a triangle, and A', B' and C' points of the sides BC, CA and AB.

Prove that the points A', B' and C' are collinear (Figure 20) if and only if they satisfy the equality:

$$\frac{\overrightarrow{A'B}}{\overrightarrow{A'C}} \cdot \frac{\overrightarrow{B'C}}{\overrightarrow{B'A}} \cdot \frac{\overrightarrow{C'A}}{\overrightarrow{C'B}} = 1.$$

<u>Obs</u>: Figure 20 — Pág. 37 (43)

Fig. 20

<u>Return</u>:

Applications. Assume that A', B' and C' are collinear.

Let A'', B'' and C'' be the symmetric points of A', B' and C' about the midpoints of the corresponding sides.

Prove that A'', B'' and C'' are collinear.

Let I, J and K be the midpoints of AA', BB' and CC'.

We want to prove that I, J and K are collinear. (12)

[12] → This result (it seems that it is due to Newton) is often stated this way: in a complete quadrilateral, here the one defined by the four lines AB, AC, BC and $B'C'$, the midpoints of the diagonals are collinear.

Let E, F and G be the midpoints of $B'C'$, AC' and AB' respectively.

Prove that $I \in FG$,

$J \in GE$ and

$K \in EF$, then that

I, J and K are collinear.

→

Solution: Pag. 303 (309) →

Exercise I.37.

The dilatation of center C' and ratio $\overrightarrow{C'A} / \overrightarrow{C'B}$ transforms B into A, that of center B' and ratio $\overrightarrow{B'C} / \overrightarrow{B'A}$ transforms A into C.

You can use their composition.

The converse statement is a consequence of the direct one.

One has $\overrightarrow{A''C} = -\overrightarrow{A'B}$, etc., thus A'', B'' and C'' satisfy the same relation as A', B' and C' do.

The points F, G and I lie on the parallel to $A'B'$ through G, etc, thus I, J and K are three points on the sides of the triangle EFG. Prove that

$$\frac{\overrightarrow{IF}}{\overrightarrow{IG}} \cdot \frac{\overrightarrow{JG}}{\overrightarrow{JE}} \cdot \frac{\overrightarrow{KE}}{\overrightarrow{KF}} = 1$$

and use Menelaüs' theorem.

Pág. 209 (215) -

Theorem 4.4 (Pascal's theorem).

Let $\mathcal{C}$ be (the image of) a proper conic and let a, b, c, d, e and f be six points of $\mathcal{C}$.

Then the intersection points of ab and de, bc and ef, cd and fa <u>are collinear.</u>

Proof. Let us give names to some of the intersection points:

$$\begin{cases} x = bc \cap ed \\ y = cd \cap ef \\ z = ab \cap de \\ t = af \cap cd \end{cases}$$

(fazer em uma elipse)

Fig. 18 →

Fig. 18 - The "mystic hexagram" of Pascal.

(see Figure 18) - Pag. 210 (216)

We want to prove that the intersection point of the lines be and ef lies on the line zt.

To do this, let us calculate the cross-ratio $[z, x, d, e]$ (these four points are collinear on the line ed):

$$[z, x, d, e] = [bz, bx, bd, be]$$

$$= [ba, bc, bd, be]$$

(these are other names for the same lines)

$$= [fa, fc, fd, fe]$$

(because f is another point of e)

$$= [t, c, d, y]$$

(using the secant cd).

$\rightarrow$

We thus have the equality

$$[z, x, d, e] = [t, c, d, y].$$

Let m be the intersection point of zt and bc.

The perspective (13)

[13] - See if necessary - Exercise V.12

Pág. 171 (177) →

Exercise V.12 (Perspectivities)

Let H and H' be two hyperplanes in the projective space $P(E)$, m a point which is neither in H nor in H'.

Let x be a point in H.

Prove that the line mx intersects H' at a unique point, that we denote by $g(x)$.

Prove that g is a projective transformation.

The mapping g is called the perspectivity of center m from

H to H' (or projection from H to H').

Prove that, if D and D' are two lines in the projective plane P and if m is a point P (neither in D nor in D'), the perspectivity of center m from D to D' is the composition of two incidences.

Sol: Exercise V.13 (Pappus, again (the most projective proof).

We use the notation of the statement of Pappus's theorem (Theorem 3.2).

Let O be the intersection point of D and D',

M that of BC' and A'C,

N that of AC' and A'B.

Consider the composition

$$f: BC' \to D' \to A'B$$

Pag. 172 (178) - cont.

of the perspectivities of center C from BC' to D' and the center A from D' to A'B. Determine f(B), f(M),

$f(C')$ and $f(\alpha)$.

Consider then the perspectivity of center B

$$g : BC' \to A'B.$$

Determine $g(B)$, $g(M)$ and $g(C')$.

Identify $g(\alpha)$ are conclude.

Solution : V 13

Pag. 322 (328) — Exercise V.13

It can immediately be checked that

$f(B) = B$,

$f(M) = A'$,

$f(C') = N$,

$f(\alpha) = Y$ on the one hand, and that

$g(B) = B$

$g(M) = A'$

$g(C') = N$ on the other.

Therefore $g = f$ and also

$g(\alpha) = \gamma$, but $g(\alpha)$ is the intersection point of

$B\alpha$ and $B'A$, thus

α, B and γ are collinear

<u>Return</u>: Solution Exercise V.12

Pág. 322 (328) →

The projective hyperplanes come from two linear hyperplanes F and F', and the point m come from a line D.

The hypothesis is that D is contained neither in F nor in F'.

Let $f : E \to E$ be the projection onto F' in the direction D.

It defines, by restriction, an isomorphism

$$f|_F : F \to F'$$

... and the projective transformation g.

The perspectivity g is also the composition of the mappings

$$H \to m^* \qquad m^* \to H'$$

and

$$x \to mx \qquad d \mapsto d \cap H',$$

where are, indeed, incidences (by definition for the second one, by duality for the first one: write $H = A^*$ for $A \in P(E^*)$, $x \in H$ is a line of $P(E^*)$ through A and mx its intersection point with m^*).

Return : Pag 210 (216)

Theorem 4.4 (Pascal's theorem)

... The perspectivity (13) of center m (from the line ed to the line cd) maps z to t, x to c, d to d and thus, as it preserves the cross-ratio, it must map e to y,

hence e, m and y are collinear.

Therefore m, which belongs to bc and zt, also belongs to ef... and this is what we wanted to prove.

Return: Solution III.51

Pág. 313 (319) →

Exercise III.51.

Use Menelaüs for the transversals mentioned in the text and use the cyclicity to write equalities such as

$$\overrightarrow{AR} \cdot \overrightarrow{BR} = \overrightarrow{CR} \cdot \overrightarrow{DR} \ldots$$

then conclude.

Audin - Geometry - (2003).pdf

Pág. 254 (260) - 2.

The curvature of a plane curve.

We assume now that $\mathcal{E}$ is an oriented affine Euclidean plane.

Let $s \mapsto f(s)$ be a curve parametrized by arc length (see if necessary §41).

The tangent vector at the point defined by s is a unit vector, that we denote $\tau(s)$.

Let $n(s)$ be the unique unit vector such that $(\tau(s), n(s))$ is a direct orthonormal basis of E.

It is called the normal vector.

Pág. 255 (261)

Differentiating the relation

$\|\tau(s)\|^2 = 1$ with respect to s, it is seen that $\tau'(s)$ is perpendicular to $\tau(s)$, therefore this vector is collinear

to $n(s)$. There exist thus a scalar $K(s)$ such that

$$\tau'(s) = K(s)\, n(s).$$

The number K is the algebraic curvature of the curve at the point of parameter s.

The word "algebraic" simply means "signed".

The sign depends on the orientation of the plane and of that given to the curve by the parameter s.

Since $\tau(s) \cdot n(s) = 0$,

we get by differentiation the equality

$$\tau'(s) \cdot n(s) + \tau(s) \cdot n'(s) = 0$$

Since $\| n(s) \|^2 = 1$,

we see similarly that

$n'(s)$ is collinear with $\tau(s)$, and thus also that

$$n'(s) = -k(s)\,T(s).$$

Pág. 257 (263) –

Proposition 3.2 (Huygen's principle)

The curve f_a has a singular point for any value of s such that $\rho(s) = a$.

The set of these singular points (when a varies) is the evolute of the curve γ.

Proof: For this calculation, we choose an origin for the affine plane, so that we consider that $f(s)$ and $f_a(s)$ are vectors.

We are looking for the singular points of γ_a that is, for the values of s for which df_a/ds is zero:

$$0 = \frac{d}{ds}\left(f(s) + a\,n(s)\right) =$$

$$T(s) + a\,n'(s) = (1 - a\,k(s))\,T(s),$$

Fig. 8
Huygens' Principle

this giving $p(s) = a$.

The set of singular points is obtained by replacing a by $p(s)$ in $f_a(s)$;

it is thus parametrized by

$$s \mapsto f(s) + p(s)\, n(s).$$

this is indeed the evolute of γ.

Obs.:

Fig. 7 - Parallel Curves.

Pág. 258 (264)

Remark 3.3 →

This proposition, illustrated by Figure 8, is known in geometrical optics under the name of "Huygens' principle".

The curve is considered as (the boundary of) a light source:

it emits straight light rays that are perpendicular to the source.

ATENÇÃO:

Estudar com Euclid's Fifth Postulate or Parallel Postulate

The parallel curve γ_a is the place reached, at the time a, by the waves emitted at the time 0; it is called a wave-front!

The evolute, envelope of the normals, is the 'caustic' of the

light curve, on which the intensity of the light concentrates.

The principle of Huygens asserts that the caustic consists of all the singular points of the wave-front.

Gauss's Law in Electrostatics and Applications

obs LHS → left-hand side (1.16)

Pág. 06 (19)

1.4 → A useful Representation of the Dirac δ-Function

Let us now integrate both sides of (1.8) over a certain volume:

$$\int (\nabla \cdot E)\, dV = \frac{1}{\epsilon_0} \int \rho\, dV.$$

We can use Gauss's theorem in vector analysis (0.13) to convert the LHS into a surface integral over the surface bounding this volume and also note that

$\int \rho \, dV$ appearing on the RHS is the total charge Q enclosed within this bounding surface.

$$\oint E \cdot dS = \frac{1}{\epsilon_0} Q. \quad (2.23)$$

The LHS of this equation is the total <u>outward</u> (para fora) eletric flux across the closed surface bounding the volume.

According to (2.23), this outward eletric flux is essentially equal to the total charge enclosed within this surface (divided by ϵ_0).

This repuet (2.23) is often referred to as

<u>GAUSS'S LAW IN ELECTROSTATICS.</u>

This law often provides a quick method for calculating the eletric field in <u>highly</u>

symmetric situations.

To illustrate how it is used, we consider an

infinite plane surface

having eletric charge σ per unit area with free space on both sides, as shown in Fig. 2.4.a.

From symmetry, we expect the eletric field lines to go out on both sides perpendicular to the plane surface.

Let us consider a cylindrical box of which the two end surfaces are parallel to the plane surface with the charge.

If A is the cross-sectional area of this cylinder, it is obvious that the total electric flux

$\oint E \cdot ds$ out of the

bounding surfaces of the cylindrical box is $2EA$. The total charge

included within this volume is

$$Q = \sigma A.$$

According to (2.23), we have

$$2EA = \frac{1}{\epsilon_0} \sigma A$$

from which

$$E = \frac{\sigma}{2\epsilon_0} \qquad (2.24)$$

→ 623 pages.
Search: parallel (13 occurrences).

Pág. 144 (169) → <u>IMPORTANT!!!</u>

Then, indeed, one has $n^2 = n_\alpha n^\alpha = -1$
It is important to express the 4-dimensional <u>curvature</u> in terms of the above (3+1) decomposition.
Concerning the 3-dimensional (intrinsic) <u>curvature</u> of a hypersurface Σ, one uses simply all the notions given in Section 1.B.1 for the case of four dimensions, by replacing the 4-metric $g_{\alpha\beta}$ with the 3-metric $\overset{3}{g}_{ij} = g_{ij}$.
The Christoffel symbols of the hypersurface $\overset{3}{\Gamma}{}^i_{jk}$ are constructed with $\overset{3}{g}_{ij}$ by

the formula (1.3.5).

Thus the Riemann tensor (1.3.2) is replaced with the 3-dimensional one, ${}^{3}R^{i}{}_{kjl}$; the Ricci tensor (1.3.3) is replaced with the 3-dimensional one, ${}^{3}R_{kl}$; and the <u>scalar curvature</u> (1.3.4.) is replaced with the 3-dimensional one, ${}^{3}R$.

However, one must note that the 3-dimensional curvature of Σ is its intrinsic curvature. Therefore, to have a full description, it is necessary to add an <u>extrinsic curvature</u>, which describes the embedding of Σ into the 4-dimensional <u>spacetime</u>.

Part I

THE SPECIAL THEORY OF RELATIVITY

CHAPTER

I. Frames of Reference, Coördinate Systems, and Coördinate Transformations 3

Coördinate transformations not involving time. Coördinate transformations involving time.

II. Classical Mechanics 8

The law of inertia, inertial systems. Galilean transformations. The force law and its transformation properties.

III. The Propagation of Light 16

The problem confronting classical optics. The corpuscular hypothesis. The transmitting medium as the frame of reference. The absolute frame of reference. The experiment of Michelson and Morley. The ether hypothesis.

IV. The Lorentz Transformation 28

The relative character of simultaneity. The length of scales. The rate of clocks. The Lorentz transformation. The "kinematic" effects of the Lorentz transformation. The proper time interval. The relativistic law of the addition of velocities. The proper time of a material body. Problems.

V. Vector and Tensor Calculus in an n Dimensional Continuum 47

Orthogonal transformations. Transformation determinant. Improved notation. Vectors. Vector analysis. Tensors. Tensor analysis. Tensor densities. The tensor density of Levi-Civita. Vector product and curl. Generalization. n dimensional continuum. General transformations. Vectors. Tensors. Metric tensor, Riemannian spaces. Raising and lowering of indices. Tensor densities, Levi-Civita tensor density. Tensor analysis. Geodesic lines. Minkowski world and Lorentz transformations. Paths, world lines. Problems.

VI. Relativistic Mechanics of Mass Points 85
Program for relativistic mechanics. The form of the conservation laws. A model example. Lorentz covariance of the new conservation laws. Relation between energy and mass. The Compton effect. Relativistic analytical mechanics. Relativistic force. Problems.

VII. Relativistic Electrodynamics 106
Maxwell's field equations. Preliminary remarks on transformation properties. The representation of four dimensional tensors in three plus one dimensions. The Lorentz invariance of Maxwell's field equations. The physical significance of the transformation laws. Gauge transformations. The ponderomotive equations.

VIII. The Mechanics of Continuous Matter 121
Introductory remarks. Nonrelativistic treatment. A special coördinate system. Tensor form of the equations. The stress-energy tensor of electrodynamics. Problem.

IX. Applications of the Special Theory of Relativity . . 133
Experimental verifications of the special theory of relativity. Charged particles in electromagnetic fields. The field of a rapidly moving particle. Sommerfeld's theory of the hydrogen fine structure. De Broglie waves. Problems.

Part II

THE GENERAL THEORY OF RELATIVITY

X. The Principle of Equivalence 151

CHAPTER XVI

Weyl's Gauge-Invariant Geometry

In the general theory of relativity, the gravitational field forms the basic geometric structure of a metric space, while the electromagnetic field is unrelated to the geometry of the space. Many attempts have been made to base a new theory of gravitation and electromagnetism on a modified geometry in which there would be room and need for another geometric object besides the metric tensor. One of the most ingenious of these attempts is undoubtedly H. Weyl's gauge-invariant geometry.[1] However, in spite of the beauty of the geometrical conception, this geometry has not led to a successful theory.

In this chapter, we shall report on Weyl's geometry and the field theories based on it. The formalism by means of which Weyl's geometry is presented here differs from Weyl's own, but is equivalent to it as far as the formation of covariants goes. All covariant formations of Weyl's formalism correspond to covariants in the representation chosen here, and vice versa. Our formalism, however, eliminates one non-invariant feature of Weyl's formalism, the gauge parameter, and the corresponding transformations, the gauge transformations.

The geometry. In a metric space, the space-time interval between two infinitesimally near world points, $d\tau$, is an invariant. To each world point belongs an invariant "cone" of directions along which $d\tau$ vanishes, the "light cone." Weyl's idea was to modify the geometry so that the invariance of the light cone would be maintained, while $d\tau$ would lose its invariant character. Whether this proposal has a basis in physical experience is open to debate. There is little doubt that the possible directions of light rays are an invariant property of physical space. But there are also "atomic clocks" which provide us with universal standards for a unit of proper time. Of course, it may be that in reality the frequency of a standard spectral line is subject to small variations, so that, strictly speaking, there are no

[1] H. Weyl, *Sitzungsber. d. Preuss. Akad. d. Wiss.*, 1918, p. 465; *Ann. d. Physik*, **59**, 101 (1919).

"In the general theory of relativity, the gravitational field forms the basic geometric structure of a metric space, while the electromagnetic field is unrelated to the geometry of the space." → O eletromagnetismo interfere na curvatura do espaço. O Universo se expande no nada, pois o nada permite a expansão do Universo. A partir do momento em que o Universo ocupa o nada, as leis fundamentais da Física passam a vigorar e a curvar o espaço.

rigorous standards for proper time measurements. Be that as it may, we shall tentatively accept Weyl's basic proposition and develop a geometry which satisfies his requirements.

The zero directions are completely determined by the *ratios* between the various components of the metric tensor. Weyl assumed, therefore, in addition to coördinate transformations, the existence of "*gauge transformations*," which multiply all components of the metric tensor by a factor which is an arbitrary function of the coördinates. The line element $d\tau$ is multiplied by the same factor and is, therefore, not "gauge invariant." It is possible to construct a geometry which is covariant with respect to both coördinate and gauge transformations.

Instead of introducing gauge transformations, we shall introduce a "normalizing condition" for the arbitrary factor of the line element, and require that the determinant of the $g_{\mu\nu}$ be equal to -1,

$$|g_{\mu\nu}| = -1. \tag{16.1}$$

This normalizing condition would not be invariant if we should preserve the transformation character of the $g_{\mu\nu}$. We shall, therefore, assume in this chapter that the $g_{\mu\nu}$ transform as the components of a tensor density of weight $-\frac{1}{2}$,

$$\overset{*}{g}_{\mu\nu} = \left|\frac{\partial \xi^{*\alpha}}{\partial \xi^{\beta}}\right|^{1/2} \frac{\partial \xi^{\iota}}{\partial \xi^{*\mu}} \frac{\partial \xi^{\kappa}}{\partial \xi^{*\nu}} g_{\iota\kappa}. \tag{16.2}$$

The line element $d\tau$,

$$d\tau^2 = g_{\mu\nu} d\xi^{\mu} d\xi^{\nu},$$

thus, loses its invariant character. The determinant can be represented as the multiple product of the metric tensor and the Levi-Civita tensor density,

$$|g_{\mu\nu}| \equiv \tfrac{1}{24}\, \overset{*}{\delta}{}^{\alpha_1\alpha_2\alpha_3\alpha_4} \cdot \overset{*}{\delta}{}^{\beta_1\beta_2\beta_3\beta_4} \cdot g_{\alpha_1\beta_1} \cdot g_{\alpha_2\beta_2} \cdot g_{\alpha_3\beta_3} \cdot g_{\alpha_4\beta_4}. \tag{16.3}$$

The Levi-Civita densities each have the weight $+1$; the determinant is, therefore, a scalar, and eq. (16.1) is an invariant condition. Because of the normalizing conditions (16.1), the metric tensor density has only nine algebraically independent components.

Analysis in gauge-invariant geometry. In order to formulate field equations in Weyl's geometry, we must again introduce an affine connection and a curvature. Since tensor densities play a major role in this geometry, we must extend the concept of covariant differentiation to tensor densities. To do this, we shall introduce a set of variables with one index, φ_μ, which enters the definition of covariant differentiation like this:

$$\mathfrak{A}^{\iota\cdots}{}_{\kappa\cdots,\sigma} = \mathfrak{A}^{\iota\cdots}{}_{\kappa\cdots,\sigma} + \Gamma_{\rho}{}^{\iota}{}_{\sigma}\mathfrak{A}^{\rho\cdots}{}_{\kappa\cdots} - \Gamma_{\kappa}{}^{\rho}{}_{\sigma}\mathfrak{A}^{\iota\cdots}{}_{\rho\cdots} - n\mathfrak{A}^{\iota\cdots}{}_{\kappa\cdots}\varphi_{\sigma}, \tag{16.4}$$

where n is the weight of the tensor density $\mathfrak{A}^{\iota\cdots}{}_{\kappa\cdots}$. To derive the transformation law of φ_μ, it is sufficient to consider the covariant derivatives of a scalar density D of weight n. These derivatives form a vector density,

$$D^*_{;\sigma^*} = \left|\frac{\partial\xi^\alpha}{\partial\xi^{*\beta}}\right|^n \frac{\partial\xi^\iota}{\partial\xi^{*\sigma}} D_{;\iota}.$$

Thus, we have

$$\left(\left|\frac{\partial\xi^\alpha}{\partial\xi^{*\beta}}\right|^n D\right)_{;\iota} \frac{\partial\xi^\iota}{\partial\xi^{*\sigma}} - n\varphi^*_\sigma \left|\frac{\partial\xi^\alpha}{\partial\xi^{*\beta}}\right|^n D = \left|\frac{\partial\xi^\alpha}{\partial\xi^{*\beta}}\right|^n (D_{;\iota} - n\varphi_\iota D) \frac{\partial\xi^\iota}{\partial\xi^{*\sigma}};$$

and, therefore,

$$n\left[\left(\log\left|\frac{\partial\xi^\alpha}{\partial\xi^{*\beta}}\right|\right)_{;\iota} \frac{\partial\xi^\iota}{\partial\xi^{*\sigma}} - \varphi^*_\sigma\right] D = -n\varphi_\iota \frac{\partial\xi^\iota}{\partial\xi^{*\sigma}} D. \tag{16.5}$$

The logarithmic derivative of the determinant can be written in a simplified form,

$$\left(\log\left|\frac{\partial\xi^\alpha}{\partial\xi^{*\beta}}\right|\right)_{;\iota} = \frac{\partial\xi^{*\beta}}{\partial\xi^\alpha}\frac{\partial\xi^{*\sigma}}{\partial\xi^\iota}\frac{\partial^2\xi^\alpha}{\partial\xi^{*\beta}\partial\xi^{*\sigma}} = -\frac{\partial\xi^\alpha}{\partial\xi^{*\beta}}\frac{\partial^2\xi^{*\beta}}{\partial\xi^\alpha\partial\xi^\iota}. \tag{16.6}$$

So we obtain finally the transformation law

$$\varphi^*_\sigma = \frac{\partial\xi^\iota}{\partial\xi^{*\sigma}}\varphi_\iota + \frac{\partial\xi^{*\beta}}{\partial\xi^\alpha}\frac{\partial^2\xi^\alpha}{\partial\xi^{*\beta}\partial\xi^{*\sigma}} = \frac{\partial\xi^\iota}{\partial\xi^{*\sigma}}\left(\varphi_\iota - \frac{\partial\xi^\alpha}{\partial\xi^{*\beta}}\frac{\partial^2\xi^{*\beta}}{\partial\xi^\alpha\partial\xi^\iota}\right). \tag{16.7}$$

In Riemannian geometry, the requirement that the covariant derivatives of the Kronecker tensor, δ^κ_ι, vanish leads to the conclusion that the $\overset{\mathrm{I}}{\Gamma}$ and the $\overset{\mathrm{II}}{\Gamma}$ (see Chapter V, p. 71) are equal. Once the concept of covariant differentiation is extended to densities, it is reasonable to postulate that the covariant derivatives of the Levi-Civita tensor density vanish. This condition establishes a relationship between the "pseudovector" φ_μ and the components of the affine connection,

$$\left.\begin{aligned}\delta^{\rho\iota_2\iota_3\iota_4}\Gamma^{\iota_1}_{\rho\sigma} + \delta^{\iota_1\rho\iota_3\iota_4}\Gamma^{\iota_2}_{\rho\sigma} + \delta^{\iota_1\iota_2\rho\iota_4}\Gamma^{\iota_3}_{\rho\sigma}\\ + \delta^{\iota_1\iota_2\iota_3\rho}\Gamma^{\iota_4}_{\rho\sigma} - \delta^{\iota_1\iota_2\iota_3\iota_4}\varphi_\sigma = 0.\end{aligned}\right\} \tag{16.8}$$

The left-hand side is skewsymmetric with respect to the four indices $\iota_1 \cdots \iota_4$, as can be shown by straightforward computation. Only those equations (16.8) are not empty in which these four indices all have different values. In the significant equations, the summation over ρ in the first term reduces to the one value $\rho = \iota_1$; likewise, in the second term, ρ equals ι_2; and so forth. The first four terms in eq. (16.8) are equal to

$$\delta^{\iota_1\iota_2\iota_3\iota_4}\Gamma_{\rho}{}^{\rho}{}_{\sigma},$$

and the conditions (16.8) reduce to the equations

$$\varphi_\sigma = \Gamma_\rho{}^\rho{}_\sigma . \tag{16.9}$$

The metric tensor density in Weyl's geometry plays a role similar to that of the metric tensor in Riemannian geometry. We shall, therefore, assume that its covariant derivatives vanish. If we assume, as before, that the components of the affine connection are symmetric in their subscripts, we obtain the equations

$$g_{\mu\nu;\rho} \equiv g_{\mu\nu,\rho} - g_{\mu\sigma}\Gamma_\nu{}^\sigma{}_\rho - g_{\sigma\nu}\Gamma_\mu{}^\sigma{}_\rho + \tfrac{1}{2}g_{\mu\nu}\varphi_\rho = 0. \tag{16.10}$$

We can solve these equations if we introduce the "contravariant metric tensor density" of weight $(+\frac{1}{2})$, $g^{\mu\nu}$,

$$g_{\iota\rho}g^{\mu\rho} = \delta_\iota^\mu . \tag{16.11}$$

The solutions of eq. (16.10) then take the form

$$\Gamma_{\iota\kappa}^\lambda = \tfrac{1}{2}g^{\lambda\sigma}(g_{\iota\sigma,\kappa} + g_{\kappa\sigma,\iota} - g_{\iota\kappa,\sigma}) + \tfrac{1}{4}g^{\lambda\sigma}(g_{\iota\sigma}\varphi_\kappa + g_{\kappa\sigma}\varphi_\iota - g_{\iota\kappa}\varphi_\sigma) \equiv \begin{pmatrix}\lambda\\ \iota\kappa\end{pmatrix}. \tag{16.12}$$

If we form the contracted affine connection, $\binom{\iota}{\iota\kappa}$, we obtain again eq. (16.9). The pseudovector φ_ι and the metric tensor density $g_{\mu\nu}$ are independent of each other and are both needed to form the components of the affine connection, $\binom{\lambda}{\iota\kappa}$.

The curvature tensor, $R_{\iota\kappa\lambda\cdot}{}^\nu$, is skewsymmetric in ι and κ, has the cyclical symmetry expressed by eq. (11.29), and satisfies the Bianchi identities, eq. (11.35), for these identities hold for *any* curvature tensor which is formed from symmetric $\Gamma_{\iota\kappa}^\lambda$. However, it does not have the other symmetry properties of the curvature tensor of Riemannian geometry. Neither is the contracted tensor $R_{\iota\kappa\lambda}{}^\iota{}_\cdot$ symmetric in the indices κ and λ. In forming the contracted Bianchi identities, we must, therefore, proceed somewhat cautiously.

Let us first contract the identities,

$$R_{\iota\kappa\sigma\cdot}{}^\nu{}_{;\lambda} + R_{\kappa\lambda\sigma\cdot}{}^\nu{}_{;\iota} + R_{\lambda\iota\sigma\cdot}{}^\nu{}_{;\kappa} \equiv 0 \tag{16.13}$$

with respect to the indices ι and ν. Thus, we obtain the equations

$$R_{\rho\kappa\sigma\cdot}{}^\rho{}_{;\lambda} + R_{\kappa\lambda\sigma\cdot}{}^\rho{}_{;\rho} + R_{\lambda\rho\sigma\cdot}{}^\rho{}_{;\kappa} = R_{\rho\kappa\sigma\cdot}{}^\rho{}_{;\lambda} + R_{\kappa\lambda\sigma\cdot}{}^\rho{}_{;\rho} - R_{\rho\lambda\sigma\cdot}{}^\rho{}_{;\kappa} \equiv 0. \tag{16.14}$$

If we now raise the index σ and contract the equations with respect to κ and σ, we obtain the equations

$$R_{\rho\sigma\cdot\cdot}{}^{\sigma\rho}{}_{;\lambda} + R_{\sigma\lambda\cdot\cdot}{}^{\sigma\rho}{}_{;\rho} - R_{\rho\lambda\cdot\cdot}{}^{\sigma\rho}{}_{;\sigma} \equiv 0, \tag{16.15}$$

in which the R-quantities are *densities*.

In Riemannian geometry, the curvature tensor is skewsymmetric in its last two indices. With the help of this skewsymmetry, it is shown that the second term and the third term of eq. (16.15) are equal. In Weyl's geometry, we cannot apply the same reasoning. To obtain the symmetry relationship of the last index pair in this geometry, we shall form the covariant curvature tensor density, $R_{\iota\kappa\lambda\mu}$. We shall introduce the symbols

$$(\iota\kappa, \lambda) = g_{\lambda\sigma}\begin{pmatrix}\sigma\\ \iota\kappa\end{pmatrix} = \tfrac{1}{2}(g_{\iota\lambda,\kappa} + g_{\kappa\lambda,\iota} - g_{\iota\kappa,\lambda}) + \tfrac{1}{4}(g_{\iota\lambda}\varphi_\kappa + g_{\kappa\lambda}\varphi_\iota - g_{\iota\kappa}\varphi_\lambda), \tag{16.16}$$

in terms of which the derivatives of the metric tensor are

$$g_{\iota\kappa,\lambda} = (\kappa\lambda, \iota) + (\iota\lambda, \kappa) - \tfrac{1}{2}g_{\iota\kappa}\varphi_\lambda. \tag{16.17}$$

With the help of the $(\iota\kappa, \lambda)$, the covariant curvature tensor density can be written in the form

$$\left.\begin{aligned} R_{\iota\kappa\lambda\mu} &= (\lambda\iota, \mu)_{,\kappa} + \tfrac{1}{2}(\lambda\iota, \mu)\varphi_\kappa - (\lambda\kappa, \mu)_{,\iota} - \tfrac{1}{2}(\lambda\kappa, \mu)\varphi_\iota \\ &\qquad + g^{\rho\sigma}[(\lambda\kappa, \rho)(\mu\iota, \sigma) - (\lambda\iota, \rho)(\mu\kappa, \sigma)] \\ &= \bar{R}_{\iota\kappa\lambda\mu} + \tfrac{1}{4}[g_{\iota\mu}\varphi_{\lambda,\kappa} - g_{\kappa\mu}\varphi_{\lambda,\iota} + g_{\lambda\mu}(\varphi_{\iota,\kappa} - \varphi_{\kappa,\iota}) \\ &\qquad + g_{\kappa\lambda}\varphi_{\mu,\iota} - g_{\iota\lambda}\varphi_{\mu,\kappa}]. \end{aligned}\right\} \tag{16.18}$$

On the right-hand side, $\bar{R}_{\iota\kappa\lambda\mu}$ stands for a number of terms which have all the algebraic symmetry properties of the Riemannian curvature tensor, while the remaining terms do not. These remaining terms have only the symmetry properties (11.28) and (11.29). If we form the expression $R_{\iota\kappa\lambda\mu} + R_{\iota\kappa\mu\lambda}$, which vanishes in Riemannian geometry, we obtain here

$$R_{\iota\kappa\lambda\mu} = -R_{\iota\kappa\mu\lambda} + \tfrac{1}{2}g_{\lambda\mu}(\varphi_{\iota,\kappa} - \varphi_{\kappa,\iota}). \tag{16.19}$$

Although φ_ι is not a vector, its skewsymmetric derivatives,

$$\varphi_{\iota\kappa} = \varphi_{\iota,\kappa} - \varphi_{\kappa,\iota}, \tag{16.20}$$

form a tensor, which can be verified with the help of eq. (16.7).

If we apply eq. (16.19) to the second term in eq. (16.15), we obtain the equation

$$R_{\rho\sigma\cdot\cdot;\lambda}^{\cdot\cdot\sigma\rho} - 2R_{\rho\lambda\cdot\cdot;\sigma}^{\cdot\cdot\sigma\rho} + \tfrac{1}{2}g^{\rho\sigma}\varphi_{\sigma\lambda;\rho} = 0. \tag{16.21}$$

However, we can introduce into eq. (16.21) the symmetric part of $R_{\rho\sigma\lambda}^{\cdot\cdot\rho}$,

$$R_{\sigma\lambda} = \tfrac{1}{2}(R_{\rho\sigma\lambda}^{\cdot\cdot\rho} + R_{\rho\lambda\sigma}^{\cdot\cdot\rho}). \tag{16.22}$$

With the help of eq. (16.18), we find that $R_{\sigma\lambda}$ and $R_{\rho\sigma\lambda}{}^{\rho}$ are connected by the equation

$$R_{\rho\sigma\lambda}{}^{\rho} = R_{\sigma\lambda} + \tfrac{1}{2}\varphi_{\lambda\sigma}\,. \tag{16.23}$$

By substituting this expression in eq. (16.21), we obtain the contracted Bianchi identities in the form

$$(R^{\lambda\sigma} - \tfrac{1}{2}g^{\lambda\sigma}R)_{;\sigma} - \tfrac{1}{4}\varphi^{\lambda\sigma}{}_{;\sigma} = 0. \tag{16.24}$$

$\varphi^{\lambda\sigma}$, by the way, is a tensor density of weight $+1$, and $\varphi^{\lambda\sigma}{}_{;\sigma}$ is, therefore, the *ordinary* divergence of $\varphi^{\lambda\sigma}$, or

$$\varphi^{\lambda\sigma}{}_{;\sigma} \equiv \varphi^{\lambda\sigma}{}_{,\sigma}\,. \tag{16.25}$$

Physical interpretation of Weyl's geometry. In Weyl's geometry, the geometric structure of space is characterized by the symmetric tensor density $g_{\mu\nu}$ and the "pseudovector" φ_μ. It appears reasonable to assume that the $g_{\mu\nu}$ represent the gravitational field, and that the φ_μ are the components of the world vector potential. In Weyl's original formalism, the φ_μ transform as a vector with respect to coördinate transformations, but are changed by a gradient when a gauge transformation is carried out. This is the historical reason for calling the addition of a gradient to the electromagnetic world vector potential a gauge transformation.

We shall now attempt to set up field equations for the $g_{\mu\nu}$ and φ_μ.

Weyl's variational principle. Weyl considered it desirable to derive the field equations as the Euler-Lagrange equations of a variational principle. We shall show that the Euler-Lagrange equations of a variational principle which is invariant with respect to coördinate transformations always satisfy the necessary number of identities.

Let us consider a variational principle of the form

$$\delta I = \delta \int_V \mathfrak{L}(y_A\,,\, y_{A,\rho}\,,\, \cdots)\, d\xi = 0, \tag{16.26}$$

where the indices $A, B \cdots$ are used to number the field variables y. If we vary the y_A so that the variations and their derivatives up to the order needed vanish on the boundary of the domain V, the variation of the integral (16.26) can be brought into the form

$$\delta I = \int_V \sum_A \mathfrak{L}^A\, \delta y_A\, d\xi, \tag{16.27}$$

and the equations

$$\mathfrak{L}^A = 0 \tag{16.28}$$

are the Euler-Lagrange equations of the variational principle (16.26) Let us now vary the variables y_A by amounts which correspond to an infinitesimal coördinate transformation,

$$\xi^{*\alpha} = \xi^\alpha + \delta\xi^\alpha(\xi^\rho). \tag{16.29}$$

If the $\delta\xi^\alpha$ and their derivatives vanish on the boundary of V, the value of I is not changed by the variation, regardless of whether eqs. (16.28) are satisfied or not.

Because of the coördinate transformation (16.29), the functions y_A undergo infinitesimal changes δy_A, which depend on the $\delta\xi^\alpha$ and on the particular type of transformation law of the y_A. Let us consider the case for which some of the y_A are the components of a contravariant vector, Y^ρ. If we carry out a coördinate transformation from ξ^α to $\xi^{*\alpha}$, the transformed vector components will be new functions of the ξ^α; in addition, the arguments of these functions, ξ^α, have to be replaced by $\xi^{*\alpha}$. If we call the *transformed* vector field components, as functions of the *original* coördinates, $\tilde{Y}^\rho(\xi^\alpha)$, we have:

$$\tilde{Y}^\rho(\xi^\alpha) = Y^\rho(\xi^\alpha) + (\delta\xi^\rho)_{,\sigma}Y^\sigma(\xi^\alpha). \tag{16.30}$$

At each world point, the quantities $\tilde{Y}^\rho(\xi^\alpha)$ equal the $Y^{*\rho}(\xi^{*\alpha})$, or

$$\tilde{Y}^\rho(\xi^\alpha) = Y^{*\rho}(\xi^{*\alpha}), \tag{16.31}$$

where ξ^α and $\xi^{*\alpha}$ are the original and the new coördinates, respectively, of the same world point. To obtain the difference between the functions $\tilde{Y}^\rho$ and $Y^{*\rho}$ for the same values of their respective arguments, we must compare $\tilde{Y}^\rho$ at the world point having the coördinates $\xi^\alpha = \overset{0}{\xi}{}^\alpha$ with $Y^{*\rho}$ at the world point having the coördinates $\xi^{*\alpha} = \overset{0}{\xi}{}^\alpha$. We have:

$$Y^{*\rho}(\overset{0}{\xi}{}^\alpha) = \tilde{Y}^\rho(\overset{0}{\xi}{}^\alpha - \delta\xi^\alpha) = \tilde{Y}^\rho(\overset{0}{\xi}{}^\alpha) - Y^\rho{}_{,\sigma}\delta\xi^\sigma; \tag{16.32}$$

and the infinitesimal changes in the functions Y^ρ are, therefore,

$$\delta Y^\rho = (\delta\xi^\rho)_{,\sigma}Y^\sigma - Y^\rho{}_{,\sigma}\delta\xi^\sigma. \tag{16.33}$$

Generally speaking, tensor and tensor density components transform according to laws of the type

$$\delta y_A = -y_{A,\sigma}\delta\xi^\sigma + \sum_B F^{B\rho}_{A\sigma} y_B(\delta\xi^\sigma)_{,\rho}, \tag{16.34}$$

where the constants $F^{B\rho}_{A\sigma}$ depend on the particular transformation laws. The transformation law of the φ_α contains one term which is not of the

type (16.34). To account for this term, we shall assume that the field variables considered transform according to a law

$$\delta y_A = -y_{A,\sigma}\delta\xi^\sigma + \sum_B F^{B\rho}_{A\sigma} y_B(\delta\xi^\sigma)_{,\rho} + G^{\rho\tau}_{A\sigma}(\delta\xi^\sigma)_{,\rho\tau}, \qquad (16.35)$$

where $G^{\rho\tau}_{A\sigma}$ are additional constants.

To express the condition that I is invariant with respect to general coördinate transformations, we have to replace δy_A in eq. (16.27) by the expression (16.35). Then δI must vanish for arbitrary $\delta\xi^\alpha$, if $\delta\xi^\alpha$ and its first and second derivatives vanish on the boundary of the domain V. We have

$$\left.\begin{aligned}\delta I = \int_V \sum_A \mathfrak{L}^A \{-y_{A,\sigma}\delta\xi^\sigma + \sum_B F^{B\rho}_{A\sigma} y_B(\delta\xi^\sigma)_{,\rho} \\ + G^{\rho\tau}_{A\sigma}(\delta\xi^\sigma)_{,\rho\tau}\}\, d\xi = 0.\end{aligned}\right\} \qquad (16.36)$$

By carrying out a number of integrations by parts, we can obtain eq. (16.36) in the form

$$\int_V \sum_A \{G^{\rho\tau}_{A\sigma}\mathfrak{L}^A{}_{,\rho\tau} - \sum_B F^{B\rho}_{A\sigma}(y_B\mathfrak{L}^A)_{,\rho} - y_{A,\sigma}\mathfrak{L}^A\}\delta\xi^\sigma\, d\xi = 0;$$

and as the $\delta\xi^\sigma$ are arbitrary in the interior of V, we find that the Euler-Lagrange equations satisfy the four differential identities

$$\sum_A \{G^{\rho\tau}_{A\sigma}\mathfrak{L}^A{}_{,\rho\tau} - \sum_B F^{B\rho}_{A\sigma}(y_B\mathfrak{L}^A)_{,\rho} - y_{A,\sigma}\mathfrak{L}^A\} = 0. \qquad (16.37)$$

Now let us proceed to the construction of a variational principle in Weyl's gauge-invariant theory. The integrand of an invariant integral must be a scalar density of the weight $+1$. The curvature scalar density,

$$R = g^{\kappa\lambda}R_{\kappa\lambda}, \qquad (16.38)$$

has the weight $+\frac{1}{2}$. The Lagrangian of a variational principle must be quadratic with respect to the curvature. There are several scalar densities of weight $+1$ which can be constructed from the components of the curvature tensor. They are:

$$R^2; \qquad R_{\kappa\lambda}R^{\kappa\lambda}; \qquad R_{\iota\kappa\lambda\mu}R^{\iota\kappa\lambda\mu}; \qquad \varphi_{\kappa\lambda}\varphi^{\kappa\lambda}. \qquad (16.39)$$

The first three are of the fourth differential order with respect to the $g_{\mu\nu}$. The most general Lagrangian of this differential order would be a linear combination of the four expressions (16.39). The variations of the ten $g_{\mu\nu}$ are not independent of one another, but are restricted by the condition that the determinant g remain normalized,

$$g_{\mu\nu}\delta g^{\mu\nu} = 0. \qquad (16.40)$$

This auxiliary condition can be taken into account with the help of the method of Lagrangian factors. The additional parameter thus entering the equations can, however, be eliminated, and we are finally left with thirteen differential equations for the thirteen variables $g_{\mu\nu}$, φ_μ [the $g_{\mu\nu}$ satisfy the condition (16.1)]. The thirteen equations satisfy the four differential identities (16.37).

There are two main objections to field equations of this type. First, the equations are of the fourth differential order in the $g_{\mu\nu}$. There is every reason to believe that equations of this high order have many more solutions than field equations of the second order, and it becomes very difficult to explain why the solutions of these hypothetical equations of the fourth order are so closely approximated in nature by the solutions of equations of the second order. Second, the Lagrangian of the variational principle is not uniquely determined, for any linear combination of the expressions (16.39) is suitable. The desired unification of the field is actually not accomplished, for there remains a distinctly "electromagnetic" scalar density (the last one), which can be introduced into the Lagrangian with an arbitrary coefficient.

The equations $G_{\mu\nu} = 0$. Einstein and the author attempted to set up field equations of the *second* differential order which would be similar in structure to the equations of the general theory of relativity.[2] They investigated in particular the differential equations

$$G_{\mu\nu} = 0, \tag{16.41}$$

which are ten equations for thirteen variables; they satisfy no differential identities, but are completely independent of one another. According to eq. (16.24), Maxwell's equations,

$$\varphi^{\mu\sigma}{}_{,\sigma} = 0, \tag{16.42}$$

are a consequence of these field equations. It turned out that these equations have a static solution with spherical symmetry and with two arbitrary parameters, which can be interpreted as mass and charge, respectively. When the φ_μ vanish, the equations (16.41) for the $g_{\mu\nu}$ are formally identical with the field equations of the general theory of relativity; the solution with vanishing charge is Schwarzschild's solution, the determinant of which happens to be equal to (-1). But if the "electric charge" does not vanish, the boundary conditions at infinity cannot be satisfied, and the deviation of the metric tensor from $\epsilon_{\rho\sigma}$ increases with increasing r. This result is convincing proof that the field equations (16.41) also fail to meet the requirements of our physical experience.

[2] This work has not been published.

CHAPTER XVII

Kaluza's Five Dimensional Theory and the Projective Field Theories

Kaluza's theory. Kaluza also attempted to create a geometry in which the gravitational and the electromagnetic potentials together would determine the structure of space.[1] While Weyl constructed a non-Riemannian geometry, Kaluza increased the number of components of the metric tensor by changing the number of dimensions. He assumed that, in addition to the four dimensions of physical space, there was a fifth dimension, which had no direct physical significance.

The number of components of a symmetric tensor of rank 2 in n dimensions is

$$N = \tfrac{1}{2}n(n + 1). \tag{17.1}$$

In a five dimensional space, the metric tensor has, therefore, fifteen components. To account for the four dimensional character of the physical world, Kaluza assumed that, with a suitable choice of coordinates, the components of the metric tensor were independent of the fifth coördinate. Finally, to reduce the number of variables by one, Kaluza assumed that in those coördinate systems in which the field variables did not depend on ξ^5, the component of the metric tensor with two indices 5 was constant and equal to unity. With these assumptions, Kaluza showed that, at least in the first approximation, the fourteen differential equations

$$G_{\mu\nu} = 0 \quad (\mu, \nu = 1 \cdots 5, \text{ exclude } G_{55} = 0) \tag{17.2}$$

were equivalent to the fourteen field equations (12.55), which determine the gravitational and the electromagnetic field, if the components of the metric tensor with one index 5 were assumed to be the electromagnetic potentials.

It was soon shown that this equivalence was not only approximate, but rigorous, if the proper combinations of metric components were accepted as the gravitational potentials.

[1] Th. Kaluza, *Sitzungsber. d. Preuss. Akad. d. Wiss.*, 1921, p. 966.

To facilitate the comparison of Kaluza's theory with other theories, we shall first develop a general formalism which is applicable to several different theories, and then return to a rigorous formulation of Kaluza's proposal.

A four dimensional formalism in a five dimensional space. Let us consider a five dimensional space with the coördinates ξ^α ($\alpha = 1, \cdots, 5$) and a metric tensor $\gamma_{\mu\nu}$. (In the remainder of this chapter and in Chapter XVIII, Greek indices shall assume the values $1 \cdots 5$, while Latin indices shall run from 1 to 4.) In this space, we shall introduce four *parameters* x^a ($a = 1 \cdots 4$), which are functions of the coördinates ξ^α. The derivatives of these four parameters with respect to the coördinates, $x^a{}_{,\alpha}$, shall be everywhere linearly independent,

$$\left.\begin{array}{r} \delta_{a_1a_2a_3a_4} \cdot \delta^{\alpha_1\alpha_2\alpha_3\alpha_4\beta} \cdot x^{a_1}{}_{,\alpha_1} \cdot x^{a_2}{}_{,\alpha_2} \cdot x^{a_3}{}_{,\alpha_3} \cdot x^{a_4}{}_{,\alpha_4} \neq 0, \\ \text{for at least one value of } \beta. \end{array}\right\} \tag{17.3}$$

These four parameters define a set of curves, $x^a = \text{const.}$, in the five dimensional space. Through every point of the five dimensional space one of these curves passes. We shall consider the curves a new invariant structure in the five dimensional space. This structure remains unchanged if we carry out a "parameter transformation,"

$$x^{*a} = f^a(x^b). \tag{17.4}$$

We shall find that it is possible to introduce quantities which transform with respect to the parameter transformations as four dimensional tensors. In the physical applications which we shall consider later, the manifold which is characterized by the parameters, x^a, is assumed to be physical space; we shall, therefore, investigate how far the "geometry" of the "space" of the x^a resembles the geometry of an ordinary four dimensional, Riemannian space.

We shall call a "*p-tensor*" (short for "parameter tensor") a set of functions of the ξ^α which are characterized by indices running from 1 to 4 and which transform with respect to parameter transformations like four dimensional tensors. The derivatives of the x^a with respect to the coördinates,

$$\gamma^a_\alpha = x^a{}_{,\alpha}, \tag{17.5}$$

are contravariant p-vectors and covariant (ordinary) vectors. With the help of these quantities, we can introduce a vector field A^a, which

consists of the tangential vectors of the curves x^a = const. and which satisfies the equations

$$\left.\begin{aligned} \gamma^c_a A^a &= 0, \\ \gamma_{\alpha\beta} A^\alpha A^\beta &= 1. \end{aligned}\right\} \tag{17.6}$$

These five conditions determine the **A**-field completely.

With the help of both the γ^a_α and the A^α, we can define a field of "reciprocal γ," γ^α_a, which satisfy these conditions

$$\left.\begin{aligned} \gamma^a_\alpha \gamma^\alpha_b &= \delta^a_b, \\ A_\alpha \gamma^\alpha_a &= 0. \end{aligned}\right\} \tag{17.7}$$

These twenty conditions determine the γ^α_a completely.

With each (ordinary) vector V^α or W_β, we can associate a scalar and a p-vector,

$$\left.\begin{aligned} V^a &= \gamma^a_\alpha V^\alpha, \\ V &= A_\alpha V^\alpha, \end{aligned}\right\} \tag{17.8}$$

and

$$\left.\begin{aligned} W_b &= \gamma^\beta_b W_\beta, \\ W &= A^\beta W_\beta. \end{aligned}\right\} \tag{17.9}$$

The scalar is the part of **V** or **W** which is parallel to **A**, while the p-vector represents the part which is normal to **A**. Conversely, we can associate with a p-vector, U^a, an ordinary vector,

$$U^\alpha = \gamma^\alpha_a U^a \tag{17.10}$$

(the summation convention is to be extended to p-indices); this vector is orthogonal to **A**, regardless of the choice of U^a [because of the last four eqs. (17.7)].

With the metric tensor $\gamma_{\alpha\beta}$ we can associate a covariant p-tensor,

$$g_{ab} = \gamma^\alpha_a \gamma^\beta_b \gamma_{\alpha\beta}, \tag{17.11}$$

which we shall call the metric p-tensor or the p-metric.

The mixed γ-quantities of both kinds and the vector A^α enable us to split up every five dimensional relationship into "four dimensional" and scalar relations. The mixed γ-quantities "project" the five dimensional space on our four dimensional one. If their product is contracted with respect to the p-indices, we obtain a typical projection tensor,

$$\left.\begin{aligned} &\gamma^a_\alpha \gamma^\beta_a = \epsilon^\beta_\alpha, \\ &\epsilon^\beta_\alpha A_\beta = 0, \qquad \epsilon^\beta_\alpha A^\alpha = 0, \qquad \epsilon^\beta_\alpha \epsilon^\gamma_\beta = \epsilon^\gamma_\alpha. \end{aligned}\right\} \tag{17.12}$$

Any vector multiplied by ϵ_α^β becomes orthogonal to **A**. It can easily be shown that ϵ_α^β can be represented by the Kronecker symbol and the vector **A**,

$$\epsilon_\alpha^\beta = \delta_\alpha^\beta - A_\alpha A^\beta. \tag{17.13}$$

The proof can be carried out by multiplying the expression $(\delta_\alpha^\beta - A_\alpha A^\beta - \epsilon_\alpha^\beta)$ by the five linearly independent sets of five components, γ_a^α, A^α. All five products,

$$(\delta_\alpha^\beta - A_\alpha A^\beta - \epsilon_\alpha^\beta)\gamma_a^\alpha = 0,$$

$$(\delta_\alpha^\beta - A_\alpha A^\beta - \epsilon_\alpha^\beta)A^\alpha = 0$$

vanish. If the products of a five-rowed matrix by five independent "vectors" vanish, the matrix is the zero matrix.

A vector can be represented by its associated p-vector and its associated scalar as follows:

$$U^\alpha = \gamma_a^\alpha U^a + A^\alpha U. \tag{17.14}$$

For, if we replace U^a and U by the expressions (17.8), we obtain for the right-hand side of eq. (17.14)

$$\gamma_a^\alpha \gamma_\beta^a U^\beta + A^\alpha A_\beta U^\beta = (\epsilon_\beta^\alpha + A^\alpha A_\beta)U^\beta = \delta_\beta^\alpha U^\beta = U^\alpha.$$

Analysis in the p-formalism. In addition to the differential covariants of a Riemannian five dimensional space, there are differential covariants peculiar to the formalism developed on the preceding pages. We shall discuss them one by one.

The inner product of the (ordinary) derivative of a p-tensor by A^α,

$$t^{i\cdots}{}_{k\cdots,\alpha}A^\alpha$$

is a p-tensor of the same type. The proof can be carried out by straightforward computation. We shall call this type of covariant differentiation A-differentiation. If the A-derivative of a p-tensor vanishes, we call the p-tensor field cylindrical with respect to the **A**-field, or, for short, A-cylindrical.

We shall now consider a few of these A-derivatives. Let us consider first the A-derivative of the metric p-tensor, $g_{mn,\alpha}A^\alpha$. We shall show that it can be represented by covariant derivatives of the **A**-field. We can replace $g_{mn,\alpha}A^\alpha$ by the expression

$$g_{mn,\alpha}A^\alpha = \gamma_m^p \gamma_n^q \cdot \gamma_\alpha^r \gamma_\theta^s g_{pq,\alpha}A^\alpha,$$

and then work on those factors to the right of the dot. We have:

$$\begin{aligned}
\gamma^r_\rho \gamma^s_\sigma g_{rs,\alpha} A^\alpha &= [(\gamma^r_\rho \gamma^s_\sigma g_{rs})_{,\alpha} - (\gamma^r_\rho \gamma^s_\sigma)_{,\alpha} g_{rs}] A^\alpha \\
&= [(\gamma_{\rho\sigma} - A_\rho A_\sigma)_{,\alpha} - (\gamma^r_{\alpha,\rho}\gamma^s_\sigma + \gamma^r_\rho \gamma^s_{\alpha,\sigma}) g_{rs}] A^\alpha \\
&= [\gamma_{\rho\sigma,\alpha} - A_{\rho,\alpha} A_\sigma - A_{\sigma,\alpha} A_\rho] A^\alpha + (\gamma^r_\alpha \gamma^s_\sigma A^\alpha{}_{,\rho} + \gamma^r_\rho \gamma^s_\alpha A^\alpha{}_{,\sigma}) g_{rs} \\
&= (\gamma_{\rho\sigma,\alpha} - A_{\rho,\alpha} A_\sigma - A_{\sigma,\alpha} A_\rho) A^\alpha + (\gamma_{\alpha\sigma} - A_\alpha A_\sigma) A^\alpha{}_{,\rho} \\
&\qquad + (\gamma_{\alpha\rho} - A_\alpha A_\rho) A^\alpha{}_{,\sigma} \\
&= (\gamma_{\rho\sigma,\alpha} - A_{\rho,\alpha} A_\sigma - A_{\sigma,\alpha} A_\rho) A^\alpha + (A_{\sigma,\rho} + A_{\rho,\sigma}) \\
&\qquad - A^\alpha (\gamma_{\alpha\sigma,\rho} + \gamma_{\alpha\rho,\sigma}) + A^\alpha (A_\sigma A_{\alpha,\rho} + A_\rho A_{\alpha,\sigma}).
\end{aligned}$$

At this point, we can combine a number of terms so that we obtain a (five dimensional) tensor expression. We shall rewrite the terms in this order:

$$\left.\begin{aligned}
\gamma^r_\rho \gamma^s_\sigma g_{rs,\alpha} A^\alpha &= (A_{\rho,\sigma} + A_{\sigma,\rho} - 2[\rho\sigma, \alpha] A^\alpha) \\
&\qquad - (A_{\rho\alpha} A_\sigma + A_{\sigma\alpha} A_\rho) A^\alpha \\
&= A_{\rho;\sigma} + A_{\sigma;\rho} - (B_\rho A_\sigma + B_\sigma A_\rho),
\end{aligned}\right\} \tag{17.15}$$

where $A_{\rho\sigma}$ and B_ρ are a tensor and a vector, respectively, which denote the expressions

$$A_{\rho\sigma} = A_{\rho,\sigma} - A_{\sigma,\rho}, \tag{17.16}$$

$$B_\sigma = A_{\rho\sigma} A^\sigma. \tag{17.17}$$

For the A-derivative of the metric p-tensor, we find the expression

$$g_{mn,\alpha} A^\alpha = \gamma^\rho_m \gamma^\sigma_n (A_{\rho;\sigma} + A_{\sigma;\rho}). \tag{17.18}$$

The square of the line element,

$$d\tau^2 = \gamma_{\alpha\beta}\, d\xi^\alpha\, d\xi^\beta,$$

equals the sum of the squares of the p-line element,

$$ds^2 = g_{ab} \gamma^a_\alpha \gamma^b_\beta\, d\xi^\alpha\, d\xi^\beta, \tag{17.19}$$

and of the component of the coördinate differential vector in the A-direction,

$$d\tau_A^2 = (A_\alpha\, d\xi^\alpha)^2.$$

Let us consider an arbitrary curve in the five dimensional space, having two end points, P_1 and P_2. If we displace the whole curve by

letting each of its points slide along an A-curve for the same distance, the p-length of the curve,

$$s_{1,2} = \int_{P_1}^{P_2} ds, \tag{17.20}$$

will remain the same if the p-metric is A-cylindric. The A-length of the curve remains the same if the vector B_ρ vanishes,

$$B_\rho = 0; \tag{17.21}$$

and the (five dimensional) length of the curve will remain unchanged if the **A**-field satisfies Killing's equation,

$$A_{\rho;\sigma} + A_{\sigma;\rho} = 0. \tag{17.22}$$

For the p-metric to be cylindric, it is sufficient that the right-hand side of eq. (17.15) vanish. This condition is weaker than Killing's equation, for the product of the right-hand side of eq. (17.15) and A^ρ vanishes identically; in other words, there are only ten algebraically different components of eq. (17.15), while Killing's equation has fifteen components. It is obvious that the cylindricity of the p-metric and the cylindricity of the "A-metric" together imply cylindricity of the (five dimensional) metric, and vice versa.

Next, we shall consider the A-derivative of the skewsymmetric p-tensor φ_{rs},

$$\varphi_{rs} = \gamma_r^\rho \gamma_s^\sigma A_{\rho\sigma}. \tag{17.23}$$

This tensor φ_{rs} will eventually be interpreted as the electromagnetic field tensor. Its A-derivative is

$$\begin{aligned}
\varphi_{rs,\alpha} A^\alpha &= \gamma_r^\rho \gamma_s^\sigma \cdot \gamma_\rho^m \gamma_\sigma^n \varphi_{mn,\alpha} A^\alpha \\
&= \gamma_r^\rho \gamma_s^\sigma \cdot [\varphi_{\rho\sigma,\alpha} - \varphi_{mn}(\gamma_\rho^m \gamma_\sigma^n)_{,\alpha}] A^\alpha, \\
\varphi_{\rho\sigma} &= \gamma_\rho^r \gamma_\sigma^s \varphi_{rs}.
\end{aligned}$$

In the square bracket, we shall eliminate the γ_ρ^m and γ_σ^n. This can be done by the following transformation:

$$\begin{aligned}
\varphi_{mn}(\gamma_\rho^m \gamma_\sigma^n)_{,\alpha} A^\alpha &= \varphi_{mn}(\gamma_{\alpha,\rho}^m \gamma_\sigma^n + \gamma_\rho^m \gamma_{\alpha,\sigma}^n) A^\alpha \\
&= -\varphi_{mn}(\gamma_\alpha^m \gamma_\sigma^n A^\alpha{}_{,\rho} + \gamma_\rho^m \gamma_\alpha^n A^\alpha{}_{,\sigma}) \\
&= \varphi_{\sigma\alpha} A^\alpha{}_{,\rho} - \varphi_{\rho\alpha} A^\alpha{}_{,\sigma}.
\end{aligned}$$

We have, therefore,

$$\varphi_{rs,\alpha} A^\alpha = \gamma_r^\rho \gamma_s^\sigma [\varphi_{\rho\sigma,\alpha} A^\alpha + \varphi_{\rho\alpha} A^\alpha{}_{,\sigma} - \varphi_{\sigma\alpha} A^\alpha{}_{,\rho}].$$

Since the product of $\varphi_{\rho\alpha}$ and A^α vanishes, we may write:

$$\varphi_{rs,\alpha}A^\alpha = \gamma_r^\rho\gamma_s^\sigma(\varphi_{\rho\sigma,\alpha} + \varphi_{\sigma\alpha,\rho} + \varphi_{\alpha\rho,\sigma})A^\alpha$$
$$= \gamma_r^\rho\gamma_s^\sigma[(\epsilon_\rho^\mu\epsilon_\sigma^\nu A_{\mu\nu})_{,\alpha} + (\epsilon_\sigma^\mu\epsilon_\alpha^\nu A_{\mu\nu})_{,\rho} + (\epsilon_\alpha^\mu\epsilon_\rho^\nu A_{\mu\nu})_{,\sigma}]A^\alpha.$$

To compute the square bracket, let us keep in mind that the cyclic derivatives of $A_{\mu\nu}$ vanish and that both indices of $A_{\mu\nu}$ cannot be multiplied by the same vector. Only those terms will contribute in which one of the two factors ϵ_ρ^μ has been replaced by δ_ρ^μ and the other by $(-A^\mu A_\rho)$. We obtain, therefore,

$$\varphi_{rs,\alpha}A^\alpha = -\gamma_r^\rho\gamma_s^\sigma[(A_{\rho\sigma}A^\mu A_\rho + A_{\rho\mu}A^\mu A_\sigma)_{,\alpha} + (A_{\alpha\mu}A^\mu A_\rho + A_{\mu\rho}A^\mu A_\alpha)_{,\sigma}$$
$$+ (A_{\sigma\mu}A^\mu A_\alpha + A_{\mu\alpha}A^\mu A_\sigma)_{,\rho}]A^\alpha$$
$$= \gamma_r^\rho\gamma_s^\sigma[(B_\sigma A_\rho - B_\rho A_\sigma)_{,\alpha} + (B_\alpha A_\rho - B_\rho A_\alpha)_{,\sigma}$$
$$+ (B_\sigma A_\alpha - B_\alpha A_\sigma)_{,\rho}]A^\alpha.$$

If the differentiations are carried out, most terms cancel, either because $B_\alpha A^\alpha$ vanishes, or because undifferentiated A_ρ are multiplied by γ_r^ρ. The final result is

$$\varphi_{rs,\alpha}A^\alpha = \gamma_r^\rho\gamma_s^\sigma(B_{\rho,\sigma} - B_{\sigma,\rho}). \tag{17.24}$$

Having considered the "A-differentiation," we shall consider another differential operation, the "*p-differentiation.*" We shall call the expression

$$V_{|a} = V_{,\alpha}\gamma_a^\alpha \tag{17.25}$$

the p-derivative of V with respect to x^a. If the function happens to be A-cylindrical, the p-derivative is the ordinary derivative of V with respect to the argument x^a. (An A-cylindrical function can be considered as a function of the parameters x^a only.)

The p-derivatives of a scalar form a p-vector.

The p-differentiations do not, in general, commute. Their commutation law is

$$V_{|ab} - V_{|ba} = V_{,\rho}(\gamma_{a|b}^\rho - \gamma_{b|a}^\rho). \tag{17.26}$$

If V is A-cylindrical, the p-differentiations, being ordinary differentiations, must commute, and the right-hand side of eq. (17.26) vanishes. The bracket is, therefore, proportional to A^ρ,

$$\gamma_{a|b}^\rho - \gamma_{b|a}^\rho = A^\rho Q_{ab}. \tag{17.27}$$

We can find Q_{ab} by multiplying eq. (17.27) by A_ρ,

$$Q_{ab} = A_\rho(\gamma_{a|b}^\rho - \gamma_{b|a}^\rho) = \gamma_b^\rho A_{\rho|a} - \gamma_a^\rho A_{\rho|b} = \gamma_a^\alpha\gamma_b^\beta A_{\beta\alpha} = \varphi_{ba}.$$

We have, therefore,

$$\gamma^{\rho}_{a|b} - \gamma^{\rho}_{b|a} = A^{\rho}\varphi_{ba}\,, \tag{17.28}$$

and

$$V_{|ab} - V_{|ba} = V_{,\rho}A^{\rho}\varphi_{ba}\,. \tag{17.26a}$$

The p-derivatives of a p-tensor are not, in general, covariant. But the skewsymmetric p-derivatives of a p-vector form a p-tensor, and the cyclic p-derivatives of a skewsymmetric p-tensor of rank 2 also have p-tensor character.

Of particular interest is the p-tensor $\varphi_{rs|t} + \varphi_{st|r} + \varphi_{tr|s}$. We can express this tensor in terms of the skewsymmetric derivatives of A_ρ,

$$\varphi_{rs|t} + \varphi_{st|r} + \varphi_{tr|s} = (\gamma^{\rho}_{r}\gamma^{\sigma}_{s}A_{\rho\sigma})_{,\tau}\gamma^{\tau}_{t} + (\gamma^{\sigma}_{s}\gamma^{\tau}_{t}A_{\sigma\tau})_{,\rho}\gamma^{\rho}_{r} + (\gamma^{\tau}_{t}\gamma^{\rho}_{r}A_{\tau\rho})_{,\sigma}\gamma^{\sigma}_{s}\,.$$

As the cyclic derivatives of $A_{\rho\sigma}$ vanish, we have left only the terms

$$\varphi_{rs|t} + \varphi_{st|r} + \varphi_{tr|s} = A_{\mu\nu}[\gamma^{\nu}_{r}(\gamma^{\mu}_{t|s} - \gamma^{\mu}_{s|t}) + \gamma^{\nu}_{s}(\gamma^{\mu}_{r|t} - \gamma^{\mu}_{t|r}) + \gamma^{\nu}_{t}(\gamma^{\mu}_{s|r} - \gamma^{\mu}_{r|s})].$$

In accordance with eq. (17.28), the skewsymmetric p-derivatives of the γ^{μ}_{t} can be eliminated, and our final result is

$$\varphi_{rs|t} + \varphi_{st|r} + \varphi_{tr|s} = \gamma^{\rho}_{r}\gamma^{\sigma}_{s}\gamma^{\tau}_{t}(B_{\rho}A_{\tau\sigma} + B_{\sigma}A_{\rho\tau} + B_{\tau}A_{\sigma\rho}). \tag{17.29}$$

We shall now define the *covariant differentiation of p-tensors.* If V^a is a *p-vector*, then it can be easily shown that the differential expressions

$$V^{a}{}_{,\rho} + \Gamma^{a}_{s\rho}V^{s}$$

form a mixed tensor (p-vector with respect to a, vector with respect to ρ) if the coefficients $\Gamma^{a}_{s\rho}$ transform according to the law

$$\Gamma^{*a}_{s\rho} = \frac{\partial\xi^{\sigma}}{\partial\xi^{*\rho}}\,\frac{\partial x^{k}}{\partial x^{*s}}\left(\frac{\partial x^{*a}}{\partial x^{i}}\,\Gamma^{i}_{k\sigma} - \gamma^{l}_{\sigma}\,\frac{\partial^{2}x^{*a}}{\partial x^{l}\,\partial x^{k}}\right). \tag{17.30}$$

There are $5 \times 4 \times 4$ quantities $\Gamma^{a}_{b\rho}$. To determine them, we must formulate an equal number of conditions. The conditions

$$\gamma^{a}_{a;\rho} = 0 \tag{17.31}$$

would be too restrictive, while

$$g_{ab;\rho} = 0 \tag{17.32}$$

would be too loose. Suitable conditions must depend on three indices, one coördinate index and two parameter indices. The conditions

$$\gamma^{a}_{a}\gamma^{a}_{s;\rho} = 0 \tag{17.33}$$

are of this type. By straightforward computation we find that these conditions are satisfied if the $\Gamma^b_{a\rho}$ take the values

$$\Gamma^b_{a\rho} = \gamma^b_\beta \gamma^\alpha_a \begin{Bmatrix} \beta \\ \alpha\rho \end{Bmatrix} - \gamma^b_{\rho|a} = \begin{Bmatrix} b \\ a\rho \end{Bmatrix}. \tag{17.34}$$

It can be shown that by this choice for the $\Gamma^b_{a\rho}$, eqs. (17.32) are satisfied, too. However, eqs. (17.31) are not satisfied, and we have, instead,

$$\gamma^a_{a;\rho} = A^\alpha A_\kappa \left(\gamma^\kappa_{a,\rho} + \begin{Bmatrix} \kappa \\ \sigma\rho \end{Bmatrix} \gamma^\sigma_a \right) = A^\alpha A_\kappa \gamma^\kappa_{a;\rho} = - \gamma^\kappa_a A^\alpha A_{\kappa;\rho}. \tag{17.35}$$

The covariant p-derivative of a tensor or p-tensor with respect to x^a shall be defined as the covariant derivative with respect to ξ^a, multiplied by γ^a_a,

$$V^a{}_{;b} = V^a{}_{|b} + \begin{Bmatrix} \alpha \\ \rho b \end{Bmatrix} V^\rho, \qquad \begin{Bmatrix} \alpha \\ \rho b \end{Bmatrix} = \begin{Bmatrix} \alpha \\ \rho\beta \end{Bmatrix} \gamma^\beta_b, \tag{17.36}$$

and

$$V^a{}_{;b} = V^a{}_{|b} + \begin{Bmatrix} a \\ sb \end{Bmatrix} V^s, \qquad \begin{Bmatrix} a \\ sb \end{Bmatrix} = \begin{Bmatrix} a \\ s\beta \end{Bmatrix} \gamma^\beta_b. \tag{17.37}$$

The $\begin{Bmatrix} a \\ sb \end{Bmatrix}$ are symmetric in s and b, and we know that the expressions $g_{ab;s}$ vanish if they are formed with the help of the expressions (17.34). It follows that the $\begin{Bmatrix} s \\ ab \end{Bmatrix}$ have the values

$$\begin{Bmatrix} s \\ ab \end{Bmatrix} = \tfrac{1}{2} g^{sr} (g_{ar|b} + g_{br|a} - g_{ab|r}). \tag{17.38}$$

We shall now turn to the various curvature tensors which we can form with the help of the different types of affine connection. The easiest method of obtaining them is to formulate the various commutation laws. We have, of course, the Riemannian commutation law,

$$V^\nu{}_{;\iota\kappa} - V^\nu{}_{;\kappa\iota} = R_{\iota\kappa\lambda}{}^\nu V^\lambda. \tag{17.39}$$

To obtain the commutation law for the differentiation of a p-vector, we need the covariant derivatives of γ^a_a. They are

$$\gamma^a_{a;\rho} = A_\alpha A^\kappa \left(\gamma^a_{\kappa,\rho} - \begin{Bmatrix} \sigma \\ \kappa\rho \end{Bmatrix} \gamma^a_\sigma \right) = A_\alpha A^\kappa \gamma^a_{\kappa;\rho} = - A_\alpha \gamma^a_\kappa A^\kappa{}_{;\rho}. \tag{17.40}$$

Thus, the commutation law is

$$\left.\begin{aligned} V^n{}_{;\iota\kappa} - V^n{}_{;\kappa\iota} &= (\gamma^n_\nu V^\nu)_{;\iota\kappa} - (\gamma^n_\nu V^\nu)_{;\kappa\iota} \\ &= \gamma^n_\nu (V^\nu{}_{;\iota\kappa} - V^\nu{}_{;\kappa\iota}) + V^\nu (\gamma^n_{\nu;\iota\kappa} - \gamma^n_{\nu;\kappa\iota}) \\ &= V^\lambda \gamma^n_\nu R_{\iota\kappa\lambda}{}^\nu + (\gamma^n_{\nu;\iota\kappa} - \gamma^n_{\nu;\kappa\iota}) V^\nu. \end{aligned}\right\} \tag{17.41}$$

The expression $\gamma^n_{\nu;\iota\kappa} - \gamma^n_{\nu;\kappa\iota}$ can be computed as follows:

$$\left.\begin{aligned}\gamma^n_{\nu;\iota\kappa} - \gamma^n_{\nu;\kappa\iota} &= (\gamma^n_\sigma A^\sigma{}_{;\kappa} A_\nu)_{;\iota} - (\gamma^n_\sigma A^\sigma{}_{;\iota} A_\nu)_{;\kappa} \\ &= (\gamma^n_{\sigma;\iota} A^\sigma{}_{;\kappa} - \gamma^n_{\sigma;\kappa} A^\sigma{}_{;\iota}) A_\nu + \gamma^n_\sigma A_\nu (A^\sigma{}_{;\kappa\iota} - A^\sigma{}_{;\iota\kappa}) \\ &\qquad + \gamma^n_\sigma (A^\sigma{}_{;\kappa} A_{\nu;\iota} - A^\sigma{}_{;\iota} A_{\nu;\kappa}) \\ &= \gamma^n_\sigma [A^\sigma{}_{;\kappa} A_{\nu;\iota} - A^\sigma{}_{;\iota} A_{\nu;\kappa} - R_{\iota\kappa\rho}{}^\sigma A^\rho A_\nu],\end{aligned}\right\} \tag{17.42}$$

for the first parenthesis in the second line vanishes. If we substitute this expression in eq. (17.41), we obtain, after a few changes,

$$\left.\begin{aligned} V^n{}_{;\iota\kappa} - V^n{}_{;\kappa\iota} &= R_{\iota\kappa l}{}^n V^l, \\ R_{\iota\kappa l}{}^n &= \gamma^n_\nu \gamma^\lambda_l (R_{\iota\kappa\lambda}{}^\nu + A^\nu{}_{;\kappa} A_{\lambda;\iota} - A^\nu{}_{;\iota} A_{\lambda;\kappa}).\end{aligned}\right\} \tag{17.43}$$

The "mixed" curvature tensor $R_{\iota\kappa l}{}^n$ can also be represented by means of the $\left\{ {b \atop a\sigma} \right\}$,

$$R_{\iota\kappa l}{}^n = \left\{ {n \atop l\iota} \right\}_{,\kappa} - \left\{ {n \atop l\kappa} \right\}_{,\iota} - \left\{ {n \atop s\iota} \right\} \left\{ {s \atop l\kappa} \right\} + \left\{ {n \atop s\kappa} \right\} \left\{ {s \atop l\iota} \right\}. \tag{17.44}$$

Next we shall set up the commutation law for the covariant p-derivatives of an (ordinary) vector:

$$\left.\begin{aligned} V^\nu{}_{;ik} - V^\nu{}_{;ki} &= \gamma^\kappa_k (\gamma^\iota_i V^\nu{}_{;\iota})_{;\kappa} - \gamma^\iota_i (\gamma^\kappa_k V^\nu{}_{;\kappa})_{;\iota} \\ &= \gamma^\iota_i \gamma^\kappa_k (V^\nu{}_{;\iota\kappa} - V^\nu{}_{;\kappa\iota}) + V^\nu{}_{;\rho} (\gamma^\sigma_k \gamma^\rho_{i;\sigma} - \gamma^\sigma_i \gamma^\rho_{k;\sigma}) \\ &= \gamma^\iota_i \gamma^\kappa_k [R_{\iota\kappa\lambda}{}^\nu V^\lambda + A_{\kappa\iota} A^\rho V^\nu{}_{;\rho}].\end{aligned}\right\} \tag{17.45}$$

A similar calculation furnishes us with the commutation law for the p-derivatives of a p-vector:

$$\left.\begin{aligned} V^n{}_{;ik} - V^n{}_{;ki} &= (\gamma^n_{\nu;ik} - \gamma^n_{\nu;ki}) V^\nu + \gamma^n_\nu (V^\nu{}_{;ik} - V^\nu{}_{;ki}) \\ &= \gamma^\iota_i \gamma^\kappa_k (R_{\iota\kappa l}{}^n V^l + A_{\kappa\iota} A^\rho V^n{}_{;\rho}) \\ &= \gamma^\iota_i \gamma^\kappa_k [(R_{\iota\kappa l}{}^n + A_{\kappa\iota} \gamma^n_\nu \gamma^\lambda_l A^\nu{}_{;\lambda}) V^l + A_{\kappa\iota} A^\rho V^n{}_{;\rho}].\end{aligned}\right\} \tag{17.46}$$

On the other hand, we can express the same commutation law by means of the $\left\{ {l \atop ik} \right\}$,

$$\left.\begin{aligned} V^n{}_{;ik} - V^n{}_{;ki} &= R_{ikl}{}^n V^l + V^n{}_{;\rho} A^\rho \varphi_{ki}, \\ R_{ikl}{}^n &= \left\{ {n \atop li} \right\}_{,k} - \left\{ {n \atop lk} \right\}_{,i} - \left\{ {n \atop si} \right\} \left\{ {s \atop lk} \right\} + \left\{ {n \atop sk} \right\} \left\{ {s \atop li} \right\}.\end{aligned}\right\} \tag{17.47}$$

Comparison of the right-hand sides of eqs. (17.47), (17.46), and (17.43) furnishes us with a relation between $R_{ikl\cdot}^{\cdot n}$ and $R_{\iota\kappa\lambda\cdot}^{\cdot\nu}$:

$$R_{ikl\cdot}^{\cdot n} = \gamma_i^\iota \gamma_k^\kappa \gamma_l^\lambda \gamma_\nu^n (R_{\iota\kappa\lambda\cdot}^{\cdot\nu} + A^\nu{}_{;\lambda} A_{\kappa\iota} + A^\nu{}_{;\kappa} A_{\lambda;\iota} - A^\nu{}_{;\iota} A_{\lambda;\kappa}). \tag{17.48}$$

Of particular importance for the application of our formalism to Kaluza's theory is the double contraction of this equation,

$$\left.\begin{aligned}
&\delta_n^i g^{kl} R_{ikl\cdot}^{\cdot n} \\
&\quad = \epsilon_\nu^\iota (\gamma^{\kappa\lambda} - A^\kappa A^\lambda)[R_{\iota\kappa\lambda\cdot}^{\cdot\nu} + A^\nu{}_{;\lambda} A_{\kappa\iota} + A^\nu{}_{;\kappa} A_{\lambda;\iota} - A^\nu{}_{;\iota} A_{\lambda;\kappa}] \\
&\quad = (\delta_\nu^\iota - A^\iota A_\nu)(\gamma^{\kappa\lambda} - A^\kappa A^\lambda) R_{\iota\kappa\lambda\cdot}^{\cdot\nu} \\
&\qquad\qquad + (\gamma^{\kappa\lambda} - A^\kappa A^\lambda)[A^\rho{}_{;\lambda} A_{\kappa\rho} + A^\rho{}_{;\kappa} A_{\lambda;\rho} - A^\rho{}_{;\rho} A_{\lambda;\kappa}] \\
&\quad = R - 2A^\kappa A^\lambda R_{\kappa\lambda} + \gamma^{\kappa\lambda}[A^\rho{}_{;\lambda} A_{\kappa\rho} + A^\rho{}_{;\kappa} A_{\lambda;\rho} - A^\rho{}_{;\rho} A_{\lambda;\kappa}] \\
&\qquad\qquad + B_\rho B^\rho \\
&\quad = R - 2A^\kappa A^\lambda R_{\kappa\lambda} + 2A^\rho{}_{;\sigma} A^\sigma{}_{;\rho} - \gamma^{\rho\sigma} A^\tau{}_{;\rho} A_{\tau;\sigma} - (A^\rho{}_{;\rho})^2 \\
&\qquad\qquad + B_\rho B^\rho.
\end{aligned}\right\} \tag{17.49}$$

In this expression, we shall put the term $(-2A^\kappa A^\lambda R_{\kappa\lambda})$ into a somewhat different form, which is

$$A^\kappa A^\lambda R_{\iota\kappa\lambda\cdot}^{\cdot\iota} = A^\kappa (A^\iota{}_{;\iota\kappa} - A^\iota{}_{;\kappa\iota}) = A^\kappa (A^\iota{}_{;\iota})_{,\kappa} - B^\iota{}_{;\iota} + A^\kappa{}_{;\iota} A^\iota{}_{;\kappa}. \tag{17.50}$$

Substituting this expression in eq. (17.49), we find that the p-curvature scalar is related to the (ordinary) curvature scalar by the equation

$$\delta_n^i g^{kl} R_{ikl\cdot}^{\cdot n} = R - \gamma^{\rho\sigma} A^\tau{}_{;\rho} A_{\tau;\sigma} - (A^\rho{}_{;\rho})^2 + B_\rho B^\rho - 2A^\kappa (A^\iota{}_{;\iota})_{,\kappa} + 2B^\iota{}_{;\iota} \tag{17.51}$$

It should be emphasized that, from the point of view of the theory of invariants, the formalism which has been developed here is nothing but the theory of a unit vector field in a metric space. The value of this presentation is that in those unified field theories which employ a five dimensional space as the background of the physical world, the four parameters x^α are assumed to represent the four coördinates of our physical experience.

A special type of coördinate system. Apart from the covariant assumptions regarding the field **A**, which characterizes a given unified field theory, most authors have restricted their presentation to a special type of coördinate system, which is characterized by the condition that the first four coördinates $\xi^1 \cdots \xi^4$ be identical with the parameters $x^1 \cdots x^4$, while the choice of the fifth coördinate is restricted by the condition that the component A^5 of **A** shall be equal to unity. The

other four components, $A^1 \cdots A^4$, vanish. Coördinate systems which satisfy these conditions will be referred to as "special coördinate systems." The only coördinate transformations which lead from one "special coördinate system" to another "special coördinate system" are of the type

$$\left.\begin{aligned} \xi^{*a} &= f^a(\xi^s), \text{ coupled with } x^{*a} = f^a(x^s) \\ \xi^{*5} &= \xi^5 + f^5(\xi^s) \end{aligned}\right\} \tag{17.52}$$

We shall call these transformations "special coördinate transformations."

In a special coördinate system, the metric tensor has the components

$$\gamma_{\alpha\beta} = \begin{Bmatrix} g_{ab} + \varphi_a\varphi_b\,, & \varphi_a \\ \varphi_b\,, & 1 \end{Bmatrix}, \quad \gamma^{\alpha\beta} = \begin{Bmatrix} g^{ab}\,, & -g^{as}\varphi_s \\ -g^{bs}\varphi_s\,, & 1 + g^{rs}\varphi_r\varphi_s \end{Bmatrix}, \tag{17.53}$$

where φ_a are the first four covariant components of $\mathbf{A}$,

$$A_p = (\varphi_r\,, 1). \tag{17.54}$$

The transformation law of g_{ab} is that of a p-tensor and, as such, independent of the function f^5, eq. (17.52). The φ_r, on the other hand, transform according to the law,

$$\varphi_r^* = \frac{\partial \xi^s}{\partial \xi^{*r}}(\varphi_s - f^5{}_{,s}). \tag{17.55}$$

These are the transformation laws of gravitational and electromagnetic potentials with respect to "coördinate" and "gauge" transformations. (The expression "gauge transformation" is not to be understood as a Weyl gauge transformation!)

The various differential operations which we have discussed in the preceding section assume special forms in the special coördinate systems. The A-differentiation turns into the differentiation with respect to ξ^5,

$$V^{i\cdots}{}_{k\cdots,\alpha}A^\alpha = V^{i\cdots}{}_{k\cdots,5}\,. \tag{17.56}$$

To obtain the expression for p-differentiation, we must first know the values of γ^a_α and γ^α_a in the special coördinate system. They are

$$\gamma^a_\alpha = \left\{\begin{array}{c|c} \alpha = 1\cdots 4 & \alpha = 5 \\ \delta^a_\alpha & 0 \end{array}\right\}, \quad \gamma^\alpha_a = \left\{\begin{array}{c|c} \alpha = 1\cdots 4 & \alpha = 5 \\ \delta^\alpha_a & -\varphi_a \end{array}\right\}. \tag{17.57}$$

For the p-differentiation, we obtain the expression

$$V_{|a} = V_{,a} - \varphi_a V_{,5}\,. \tag{17.58}$$

The p-tensor φ_{rs} takes the form

$$\varphi_{rs} = \gamma_r^\rho \gamma_s^\sigma A_{\rho\sigma} = \varphi_{r,s} - \varphi_{s,r} - \varphi_s \varphi_{r,5} + \varphi_r \varphi_{s,5} . \tag{17.59}$$

The vector B_ρ has the components

$$B_\rho = (\varphi_{\rho,5}, 0), \tag{17.60}$$

and the scalar $A^\rho{}_{;\rho}$ becomes

$$A^\rho{}_{;\rho} = A^\rho{}_{,\rho} + \begin{Bmatrix} \rho \\ \sigma\rho \end{Bmatrix} A^\sigma = \begin{Bmatrix} \rho \\ 5\rho \end{Bmatrix} = \tfrac{1}{2}\gamma^{\rho\sigma}\gamma_{\rho\sigma,5} = \tfrac{1}{2}(\log|\gamma_{\alpha\beta}|)_{,5} .$$

The determinant $|\gamma_{\alpha\beta}|$ can be expressed by the g_{rs} only. If we multiply the last column of the components of $\gamma_{\alpha\beta}$, eq. (17.53), by each of the four quantities φ_b in turn and subtract the resulting columns from the first four, we obtain

$$|\gamma_{\alpha\beta}| = \begin{vmatrix} g_{ab} + \varphi_a\varphi_b , & \varphi_a \\ \varphi_b \quad , & 1 \end{vmatrix} = \begin{vmatrix} g_{ab} , & \varphi_a \\ 0 \ , & 1 \end{vmatrix} = |g_{ab}|. \tag{17.61}$$

We find, therefore, for $A^\rho{}_{;\rho}$

$$A^\rho{}_{;\rho} = \tfrac{1}{2}(\log|g_{rs}|)_{,5} = \tfrac{1}{2}g^{rs}g_{rs,5} . \tag{17.62}$$

In a special coördinate system, the derivatives of an A-cylindric p-tensor with respect to ξ^5 vanish. *If the derivatives of an (ordinary) tensor with respect to ξ^5 vanish in a special coördinate system, they vanish in every special coördinate system, and we shall call such a five dimensional tensor A-cylindric.*

It turns out that the (ordinary) derivatives of a tensor with respect to ξ^5 form a tensor of the same type. In terms of general coördinate systems, these differential formations are

$$\left.\begin{aligned} V^{\iota\cdots}{}_{\kappa\cdots,5} &= V^{\iota\cdots}{}_{\kappa\cdots,\rho} A^\rho - A^\iota{}_{,\rho} V^{\rho\cdots}{}_{\kappa\cdots} - \cdots \\ &\qquad\qquad + A^\rho{}_{,\kappa} V^{\iota\cdots}{}_{\rho\cdots} + \cdots \\ &= V^{\iota\cdots}{}_{\kappa\cdots;\rho} A^\rho - A^\iota{}_{;\rho} V^{\rho\cdots}{}_{\kappa\cdots} - \cdots \\ &\qquad\qquad + A^\rho{}_{;\kappa} V^{\iota\cdots}{}_{\rho\cdots} + \cdots . \end{aligned}\right\} \tag{17.63}$$

If this tensor vanishes, we call the tensor $V^{\iota\cdots}{}_{\kappa\cdots}$ A-cylindrical. As previously, we find that the metric tensor $\gamma_{\alpha\beta}$ is A-cylindrical if Killing's equation, (17.22), is satisfied. According to the extended definition of A-cylindricity, the γ^a_a are A-cylindrical, while the γ^α_a in general are not.

Covariant formulation of Kaluza's theory. We obtain Kaluza's restrictions of the five dimensional metric by assuming that the (five

dimensional) metric is A-cylindrical, that is, that A_ρ satisfies Killing's equation, (17.22). As a consequence, the vector B_ρ vanishes, and the A-curves are geodesics. From eq. (17.18), it follows that the p-metric is also A-cylindrical.

Furthermore, we find that φ_{rs} is A-cylindrical, because of eq. (17.24). In the p-tensor $(\varphi_{rs|t} + \varphi_{st|r} + \varphi_{tr|s})$, the strokes can be replaced by commas—ordinary differentiation with respect to the parameter x^a—and this p-tensor vanishes, because of eq. (17.29),

$$\varphi_{rs,t} + \varphi_{st,r} + \varphi_{tr,s} = 0. \tag{17.64}$$

This set of equations is just the condition which must be satisfied if the φ_{rs} are to be the skewsymmetric derivatives of four functions, Φ_r. These four functions are determined by the φ_{rs} except for an arbitrary additive gradient.

If we employ a "special coördinate system," we find that the quantities φ_r are independent of ξ^5, because of eq. (17.60), and that the φ_{rs} are their skewsymmetric derivatives,

$$\varphi_{rs} = \varphi_{r,s} - \varphi_{s,r}, \tag{17.65}$$

because of eq. (17.59).

We find that in Kaluza's theory, if we use a special coördinate system, both the g_{rs} and the φ_r are independent of ξ^5, and that the skewsymmetric derivatives of the φ_r form a p-tensor. If we do not use a special coördinate system, the quantities φ_r are not defined, but the p-tensor φ_{rs}, nevertheless, satisfies the second set of Maxwell's equations, (17.64), and both the g_{rs} and the φ_{rs} are functions of the *four* arguments x^a only. g_{rs} and φ_{rs} have, therefore, all the properties of gravitational potentials and electromagnetic field intensities, respectively, in the general theory of relativity.

To obtain field equations, Kaluza assumed that the five dimensional curvature scalar R, multiplied by the square root of the determinant $|\gamma_{\alpha\beta}|$, was the Lagrangian of a variational principle. The five dimensional curvature scalar is connected with the p-curvature scalar by eq. (17.51). Since B_ρ vanishes in Kaluza's theory, and since only the skewsymmetric parts of the covariant derivatives of A_ρ do not vanish, eq. (17.51) reduces to the equation

$$R = \delta^i_n g^{kl} R_{ikl}{}^n + \tfrac{1}{4} A_{\rho\sigma} A^{\rho\sigma} = \delta^i_n g^{kl} R_{ikl}{}^n + \tfrac{1}{4}\varphi_{rs}\varphi^{rs}. \tag{17.66}$$

If we use a special coördinate system, the determinant $|\gamma_{\alpha\beta}|$ may be replaced by $|g_{ab}|$, because of eq. (17.61); and since the Lagrangian is A-cylindrical, the integral may be taken either over a five dimen-

sional domain of the coördinates ξ^α or over a four dimensional domain of the parameters x^α. Kaluza's variational principle is, therefore,

$$\delta \int (\delta^i_n g^{kl} R_{ikl}{}^n + \tfrac{1}{4}\varphi_{rs}\varphi^{rs})\sqrt{-g}\, d\mathbf{x} = 0, \tag{17.67}$$

where the variation is subject to the conditions

$$(\delta g^{rs})_{,5} = 0, \qquad (\delta\varphi_r)_{,5} = 0. \tag{17.68}$$

This variational principle is identical with eq. (12.56), and the resulting field equations are those of the general theory of relativity (with an electromagnetic field).

Projective field theories. Kaluza introduced the fifth dimension solely for the purpose of increasing the number of components of the metric tensor, and assigned to it no real significance. A similar procedure is employed in the so-called projective geometries, which represent an n dimensional space by means of $(n + 1)$ homogeneous coordinates. In projective geometry, all those "projective points," the $(n + 1)$ homogeneous coördinate values of which have the same ratios, are considered to be "the same" point. Several authors, particularly Veblen and Hoffmann[2] and Pauli,[3] applied the same principle in their unified field theories. Our general formalism is applicable to their theories, but the geometric interpretation is different. The five dimensional coördinates are to be considered as "projective coördinates," while the real space is the four dimensional space of the parameters x^α. Each "projective" A-curve is only one point in the real space. The metric, therefore, is assumed to be A-cylindrical as a matter of course. From the point of view of our general formalism, there is no difference between the theories of Kaluza, Veblen and Hoffmann, and Pauli. The field equations are the same in all three theories. But each of these three theories was presented by its authors in a different type of coördinate system.

We have already studied Kaluza's special coördinate systems. To identify his coördinates, we shall denote them by $x^1 \cdots x^4$, $x^0 (= \xi^5)$. Veblen and Hoffmann chose a type of coördinate system which is more frequently encountered in projective geometry. It is related to Kaluza's coördinates by the equations

$$\left.\begin{aligned} \xi^s &= x^s, \\ \xi^5 &= e^{x^0}. \end{aligned}\right\} \tag{17.69}$$

[2] O. Veblen, *Projektive Relativitätstheorie*, Berlin, Springer, 1933, part of "Ergebnisse d. Mathematik u. ihrer Grenzgebiete." Contains bibliography.

[3] W. Pauli, *Ann. d. Physik*, **18**, 305 (1933); **18**, 337 (1933).

In such a coördinate system, the components of the metric tensor become

$$\left.\begin{aligned} \gamma_{55} &= e^{-2x^0}, \\ \gamma_{5a} &= \varphi_a e^{-x^0}, \\ \gamma_{ab} &= (g_{ab} + \varphi_a \varphi_b). \end{aligned}\right\} \tag{17.70}$$

Apart from transformations of the first four coördinates among themselves, their choice of coördinates permits transformations of the type

$$\xi^{*5} = F(x^a) \cdot \xi^5. \tag{17.71}$$

With respect to these transformations, the components of the metric tensor transform according to the equations

$$\left.\begin{aligned} \overset{*}{\gamma}_{55} &= \frac{1}{F^2}\gamma_{55} = \frac{1}{F^2} e^{-2x^0}, \\ \overset{*}{\gamma}_{5a} &= \frac{1}{F}[A_a - (\log F)_{,a}]e^{-x^0}, \\ \overset{*}{g}_{ab} &= g_{ab}. \end{aligned}\right\} \tag{17.72}$$

Pauli chose a type of coördinate system which can properly be called homogeneous. His coördinates are related to Kaluza's by the equations

$$X^a = f^a(x^s)e^{x^0}, \tag{17.73}$$

$$\left.\begin{aligned} x^a &= \overset{(0)}{h}{}^a(X^s), \\ x^0 &= \log \overset{(1)}{h}(X^s), \end{aligned}\right\} \tag{17.74}$$

where $\overset{(0)}{h}{}^a$ are four *homogeneous* functions of the zeroth degree,

$$\overset{(0)}{h}{}^a(\alpha X^s) = \overset{(0)}{h}{}^a(X^s), \tag{17.75}$$

and $\overset{(1)}{h}(X^s)$ is a homogeneous function of the first degree,

$$\overset{(1)}{h}(\alpha X^s) = \alpha \overset{(1)}{h}(X^s). \tag{17.76}$$

Transitions from one homogeneous coördinate system to another are accomplished by means of homogeneous transformation equations of the first degree,

$$X^{*s} = \overset{(1)}{H}{}^s(X^s). \tag{17.77}$$

The contravariant components of the vector **A** in homogeneous coördinates are

$$A^\rho = \frac{\partial X^\rho}{\partial x^0} = X^\rho. \tag{17.78}$$

In Pauli's formalism, the coördinates themselves have vector character and are identical with the components A^ρ.

The A-cylindricity of tensors finds a very peculiar expression in Pauli's coördinate system. In terms of Kaluza's coördinates, an A-cylindrical tensor is independent of the coördinate x^0. When we go over to Pauli's coördinates, a tensor $V_{\alpha\cdots}{}^{\beta\cdots}$ transforms according to the law

$$V^*_{\alpha\cdots}{}^{\beta\cdots} = \frac{\partial X^\beta}{\partial x^\sigma} \cdots \frac{\partial x^\rho}{\partial X^\alpha} \cdots V_{\rho\cdots}{}^{\sigma\cdots} .$$

$V_{\rho\cdots}{}^{\sigma\cdots}$ are functions of $x^1 \cdots x^4$ only and, therefore, homogeneous functions of the zeroth degree of the X^ρ. Each coefficient $\frac{\partial X^\beta}{\partial x^\sigma}$ is a function of $x^1 \cdots x^4$, multiplied by e^{x^0}, and, therefore, homogeneous of the first degree in the X^ρ. Conversely, the coefficients $\frac{\partial x^\rho}{\partial X^\alpha}$ are each homogeneous of the (-1)st degree in the X^ρ. *An A-cylindrical tensor is homogeneous, and the degree of its homogeneity equals the difference between the number of its contravariant and of its covariant indices.*

CHAPTER XVIII

A Generalization of Kaluza's Theory

Possible generalizations of Kaluza's theory. Kaluza's theory appeared to be a very attractive starting point for a modification of the general theory of relativity, though it did not lead to new field equations nor solve any of the unsolved problems of theoretical physics. But it suggested several avenues of approach to a new theory which would make gravitational and electromagnetic fields parts of one unified field.

One generalization of Kaluza's theory was attempted by Einstein and Mayer.[1] They assumed, as did Kaluza, that physical space was four dimensional, but they introduced five dimensional tensor calculus without, at the same time, introducing a five dimensional space and a five dimensional coördinate system. They assumed that there were tensors, with indices running from 1 to 5, the components of which were functions of four coördinates only. Apart from four dimensional coördinate transformations, there were to be transformations of the "five dimensional tensors," with transformation matrices $M_\alpha{}^\beta$ and $M^\alpha{}_\beta$, so that, for instance, "five dimensional" vectors transformed according to the equations

$$\left.\begin{aligned} V^{*\alpha} &= M^\alpha{}_\beta V^\beta \\ W^*_\alpha &= M_\alpha{}^\beta W_\beta, \qquad M^\alpha{}_\beta M_\gamma{}^\beta = \delta^\alpha_\gamma, \end{aligned}\right\} \tag{18.1}$$

where the $M^\alpha{}_\beta$ were *arbitrary* functions of the four coördinates. If the existence of a five dimensional coördinate system had been assumed, the matrices $M^\alpha{}_\beta$ would be partial derivatives of the new coördinates with respect to the old ones,

$$M^\alpha{}_\beta = \frac{\partial \xi^{*\alpha}}{\partial \xi^\beta},$$

and as such subject to differential identities,

$$M^\alpha{}_{\beta,\sigma} - M^\alpha{}_{\sigma,\beta} = M^\alpha{}_{\beta,\lambda}\gamma^\lambda_\sigma - M^\alpha{}_{\sigma,\lambda}\gamma^\lambda_\beta = 0.$$

[1] *Berl. Ber.*, 1931, p. 541; *Berl. Ber.*, 1932, p. 130.

Nothing of this kind is assumed in the Einstein-Mayer theory. A number of the differential covariants of the Kaluza theory, therefore, have no counterpart in the Einstein-Mayer theory. While they also introduce quantities γ^a_α and γ^α_a to lead from five dimensional tensors to four dimensional ones, and vice versa, the expressions

$$\gamma^a_{\alpha,\beta} - \gamma^a_{\beta,\alpha} = \gamma^a_{\alpha,b}\gamma^b_\beta - \gamma^a_{\beta,b}\gamma^b_\alpha,$$

which vanish in the Kaluza theory, do not in general vanish in the Einstein-Mayer theory and are not even covariant. The expressions

$$\gamma^\alpha_{a,\beta} - \gamma^\alpha_{b,\alpha},$$

which are covariant in the Kaluza theory, are not covariant in the Einstein-Mayer theory. On the other hand, in the Einstein-Mayer theory there are a number of differential covariants the counterparts of which in the Kaluza theory vanish identically. In fact, there are many more of them than can be interpreted in a physical theory.

It is also possible to generalize Kaluza's theory by relaxing the condition of A-cylindricity. This was done by Einstein and Bergmann, and later by Einstein, Bargmann, and Bergmann, in two papers which will be reported on briefly in this chapter.[2] †

The geometry of the closed, five dimensional world. While the projective theories, and particularly the Einstein-Mayer theory, consider space as four dimensional, and introduce the fifth dimension only as a means of constructing a new type of tensor calculus, the theory presented in the two papers mentioned above was designed to give the fifth dimension a stronger physical significance.

Physical considerations motivated the development of this theory. It appeared impossible for an ironclad four dimensional field theory ever to account for the results of quantum theory, in particular, for Heisenberg's indeterminacy relation. Since the description of a five dimensional world in terms of a four dimensional formalism would be incomplete, it was hoped that the indeterminacy of "four dimensional" laws would account for the indeterminacy relation and that quantum phenomena would, after all, be explained by a field theory. It appears fairly certain today that these high hopes were unjustified. Whether any part of the five dimensional approach will stand the test of time remains to be seen.

---

†See Appendix B.

The macroscopic world, at any rate, is four dimensional, and the five dimensional world must be, at least approximately, cylindrical with respect to the fifth dimension. Einstein and his collaborators assumed, therefore, that the world was *closed* with respect to the fifth dimension and formed what might be called a tube.

If we cut out of a five dimensional continuum a thin slice of infinite extension and identify the two open (four dimensional) faces of the slice, we shall have a model of such a closed five dimensional space. All field functions are, of course, supposed to be continuous across the "seam"; and, therefore, if the tube is sufficiently narrow (that is, if the slice is sufficiently thin), the variation of a field quantity around the tube will be small compared with its variation along the tube.

The closed five dimensional space is assumed to have Riemannian geometry. In addition, it is subject to another restriction which reduces the number of field variables from 15 to 14. In treating Kaluza's theory, we called the metric of his theory A-cylindrical. In other words, Kaluza's space is cylindrical not only with respect to *some* vector field, but to a *unit* vector field, **A**. Because of this, the A-curves of Kaluza turn out to be geodesics, and in a special coördinate system, γ_{55} equals unity. In the geometry which we are discussing at present, Kaluza's cylindricity condition is replaced by the condition that the five dimensional space be closed. In addition, it is assumed that those geodesics which connect a point with itself around the tube intersect themselves at an angle zero, in other words, that they are continuous, closed lines. This assumption takes the place of Kaluza's condition that his space be cylindrical with respect to a *unit* vector field.

Exactly one of the closed geodesic lines goes through each point of the five dimensional space. The length of such a line, taken once around the tube and back to the starting point, shall be called the "*circumference*" of the space in the fifth dimension. We shall now prove that *this circumference is everywhere the same.*

Let us consider a closed geodesic line passing through the point P. Its length S equals

$$S = \int_P^P \sqrt{\gamma_{\iota\kappa} \frac{d\xi^\iota}{dp} \frac{d\xi^\kappa}{dp}}\, dp = \int_P^P \sqrt{\gamma_{\iota\kappa} \xi^{\iota\prime} \xi^{\kappa\prime}}\, dp, \qquad (18.2)$$

where p is an arbitrary function of the coördinates; the path of integration is a closed geodesic line. Let us now vary the coördinates of every point along the closed geodesic line by infinitesimal amounts $\delta\xi^\iota$, so that

we obtain a new line. The "end point" P is not to be kept fixed. The difference between the length of the new and the old lines is

$$\left.\begin{aligned}\delta S &= \int_P^P \frac{\frac{1}{2}\gamma_{\iota\kappa,\rho}\xi^{\iota\prime}\xi^{\kappa\prime}\delta\xi^\rho + \gamma_{\iota\rho}\xi^{\iota\prime}\delta\xi^{\rho\prime}}{\sqrt{\gamma_{\iota\kappa}\xi^{\iota\prime}\xi^{\kappa\prime}}}\,dp \\ &= \int_P^P \{\tfrac{1}{2}\gamma_{\iota\kappa,\rho}\dot{\xi}^\iota\dot{\xi}^\kappa\delta\xi^\rho + \gamma_{\iota\rho}\dot{\xi}^\iota\dot{\delta\xi}^\rho\}\,d\tau,\end{aligned}\right\} \tag{18.3}$$

where the dots denote differentiation with respect to τ, the arc length from P. By integrating by parts, we obtain

$$\left.\begin{aligned}\delta S &= \int_P^P \{\tfrac{1}{2}\gamma_{\iota\kappa,\rho}\dot{\xi}^\iota\dot{\xi}^\kappa - \gamma_{\iota\rho,\kappa}\dot{\xi}^\iota\dot{\xi}^\kappa\delta\xi^\rho - \gamma_{\iota\rho}\ddot{\xi}^\iota\delta\xi^\rho\}\,d\tau + \overset{P}{\underset{P}{[}}\gamma_{\iota\rho}\dot{\xi}^\iota\delta\xi^\rho] \\ &= -\int_P^P \gamma_{\iota\rho}\left(\ddot{\xi}^\iota + \left\{{\iota \atop \kappa\lambda}\right\}\dot{\xi}^\kappa\dot{\xi}^\lambda\right)\delta\xi^\rho\,d\tau + \overset{P}{\underset{P}{[}}\gamma_{\iota\rho}\dot{\xi}^\iota\delta\xi^\rho].\end{aligned}\right\} \tag{18.4}$$

The contents of the parenthesis vanish, because the original line is geodesic. The variation of S depends, therefore, only on the coördinate variations at the double end point,

$$\delta S = \overset{P}{\underset{P}{[}}\gamma_{\iota\rho}\dot{\xi}^\iota\delta\xi^\rho]. \tag{18.5}$$

The expression in the square bracket is the scalar product of the two vectors $\dot{\xi}^\iota$ and $\delta\xi^\rho$, and thus invariant. Since the $\delta\xi^\rho$ at the two boundaries actually represent the same infinitesimal displacement, and the $\dot{\xi}^\iota$ the same direction, the contributions of the two boundaries cancel, and δS vanishes. If we proceed, by successive variations, from one closed geodesic line to another, so that all the intermediate lines are also geodesics, S will remain constant during this process.

The circumference of a closed space, in which all self-intersecting geodesics are closed lines without discontinuities of direction, is thus a characteristic constant of that space.

The tangential vectors of the closed geodesics, $\dfrac{d\xi^a}{d\tau}$, form a field of unit vectors. We shall call this unit vector field **A** and apply to the closed five dimensional continuum the formalism which was developed in the preceding chapter.

Since the **A**-field consists of the tangential vectors of geodesics, it satisfies the differential equations

$$A^a{}_{;\rho}A^\rho = 0, \tag{18.6}$$

which means, according to eqs. (17.17) and (17.21), that the A-metric,

$$d\tau_A = A_\alpha \, d\xi^\alpha, \tag{18.7}$$

is A-cylindrical. Eq. (18.6) takes a particularly simple form in a special coördinate system.

Introduction of the special coördinate system. In a special coördinate system, **A** has the contravariant components (0, 0, 0, 0, 1) and the covariant components (γ_{5s}, 1). Eq. (18.6), therefore, takes the form

$$A^\alpha{}_{,5} + \begin{Bmatrix} \alpha \\ 55 \end{Bmatrix} = 0 \tag{18.8}$$

or

$$\left.\begin{aligned} \begin{Bmatrix} \alpha \\ 55 \end{Bmatrix} = 0, \qquad [55, \alpha] = 0, \\ \gamma_{\alpha 5,5} - \tfrac{1}{2}\gamma_{55,\alpha} = 0. \end{aligned}\right\} \tag{18.8a}$$

Since, in a special coördinate system, γ_{55} is constant and equal to unity, eq. (18.6) becomes finally

$$\gamma_{\alpha 5,5} = \varphi_{\alpha,5} = 0; \tag{18.9}$$

in other words, *the quantities φ_s do not depend on ξ^5.*

The remaining components of the metric tensor are periodic in ξ^5, for the A-curves are closed curves, and return to a point through which they have passed once. The coördinate distance of a point from itself (around the tube) equals the metric distance, because γ_{55} equals unity; it is, thus, the same for every point in the space considered. *All* fields which are uniquely defined in our closed space are periodic functions of ξ^5 with the period S, eq. (18.2).

In a special coördinate system, the five dimensional metric thus decomposes into a set of ten functions g_{mn},

$$g_{mn} = \gamma_{mn} - \varphi_m \varphi_n, \tag{18.10}$$

which are periodic in ξ^5 with the period S, and into four functions φ_m, which depend only on $\xi^1 \cdots \xi^4$.

Because of eq. (18.9), the vector B_s, eqs. (17.17) and (17.60), vanishes, and the only tensors of the first differential order are

$$\varphi_{rs} = \varphi_{r,s} - \varphi_{s,r} \tag{18.11}$$

[because of eq. (17.59)] and

$$g_{mn,5} = A_{m;n} + A_{n;m} \tag{18.12}$$

[because of eq. (17.18)].

The derivation of field equations from a variational principle. Einstein and his collaborators formulated two different sets of field equations which are based on the geometry of a closed five dimensional space with closed coördinates. In this section, we shall discuss the first of these two sets.

We can set up field equations which are the Euler-Lagrange equations of a variational principle. There are four different scalars of the second differential order, each of which makes a different contribution to the field equations. They are:

$$\left.\begin{aligned} &\delta^i_n g^{kl} R_{ikl}{}^n; \qquad \varphi_{rs}\varphi^{rs}; \qquad (A_{\mu;\nu} + A_{\nu;\mu})(A_{\rho;\sigma} + A_{\sigma;\rho})\gamma^{\mu\nu}\gamma^{\rho\sigma}; \\ &(A_{\mu;\nu} + A_{\nu;\mu})(A_{\rho;\sigma} + A_{\sigma;\rho})\gamma^{\mu\rho}\gamma^{\nu\sigma}. \end{aligned}\right\} \tag{18.13}$$

All other scalars of the second differential order differ from a linear combination of these four only by divergences, which do not contribute to the Euler-Lagrange equations. A linear combination of these four scalars, multiplied by the square root of the negative determinant $\sqrt{-|\gamma_{\rho\sigma}|}$ (or, in the case of a special coördinate system, by $\sqrt{-g}$) and integrated over a five dimensional domain of the coördinates $\xi^1 \cdots \xi^5$, is an invariant.

The variation of such an integral,

$$I = \int H\sqrt{-g}\,\mathrm{d}\xi, \tag{18.14}$$

must preserve the typical geometrical properties of the closed space; that is, if we use a special coördinate system, the variations of the φ_r must be independent of ξ^5, and the variations of the g_{mn} must be periodic in ξ^5 with the period S. We cannot require, therefore, that the variations of the φ_r and g^{rs} vanish everywhere on the boundary of an arbitrary domain of integration. However, the variation on the boundary will not contribute to the variation of the integral if the domain extends exactly once around the tube, or, in other words, over one period of ξ^5, and if δg^{rs} and $\delta\varphi_s$ vanish on that part of the boundary which is generated by A-curves. The variation will, thus, have the form

$$\left.\begin{aligned} &\delta \int H\sqrt{-g}\,d\xi^1 \cdots d\xi^5 \\ &\qquad = \int \{Q_{rs}\,\delta g^{rs} + J^s\,\delta\varphi_s\}\sqrt{-g}\,d\xi^1 \cdots d\xi^5, \end{aligned}\right\} \tag{18.15}$$

provided that the domain of integration extends over one period (or an integral number of periods) of ξ^5, and provided that the δg^{rs} and $\delta\varphi_s$

vanish on the significant part of the boundary of the domain. The $\delta\varphi_s$ are independent of ξ^5; the δg^{rs} are periodic functions of ξ^5, but locally arbitrary. The integral I will be stationary if these equations are satisfied:

$$\left.\begin{aligned} Q_{rs} &= 0, \\ \int_{\xi^5=0}^{S} J^s \sqrt{-g}\, d\xi^5 &= 0. \end{aligned}\right\} \tag{18.16}$$

We cannot require that the expressions J^s vanish everywhere, for if the integral (18.16), which is to be extended once around an A-curve, vanishes, the variations of φ_s, which are constant along each A-curve, will not contribute to δI.

The integro-differential equations (18.16) satisfy five integro-differential identities. If we carry out an infinitesimal special coördinate transformation,

$$\left.\begin{aligned} \xi^{*a} &= \xi^a + \delta\xi^a(\xi^s), \\ \xi^{*5} &= \xi^5 + \delta\xi^5(\xi^s), \end{aligned}\right\} \tag{18.17}$$

the field variables g^{rs} and φ_s transform as follows:

$$\begin{aligned} \delta g^{rs} &= g^{rt}(\delta\xi^s)_{,t} + g^{ts}(\delta\xi^r)_{,t} - \delta\xi^t g^{rs}{}_{,t} - \delta\xi^5 g^{rs}{}_{,5}, \\ \delta\varphi_s &= -\varphi_t(\delta\xi^t)_{,s} - (\delta\xi^5)_{,s} - \delta\xi^t\varphi_{s,t}, \end{aligned}$$

or

$$\left.\begin{aligned} \delta g^{rs} &= g^{rt}(\delta\xi^s)_{;t} + g^{st}(\delta\xi^r)_{;t} - g^{rs}{}_{,5}(A_\rho\,\delta\xi^\rho), \\ \delta\varphi_s &= -\varphi_{st}\delta\xi^t - (A_\rho\,\delta\xi^\rho)_{,s}, \\ A_\rho\,\delta\xi^\rho &= \varphi_t\delta\xi^t + \delta\xi^5. \end{aligned}\right\} \tag{18.18}$$

If we choose a set of $\delta\xi^a$ which vanish on the significant part of the boundary of the domain of integration, the variation of I on account of this infinitesimal transformation must vanish, even if eqs. (18.16) are not satisfied,

$$\left.\begin{aligned} 0 &= \int \{Q_{rs}[g^{rt}(\delta\xi^s)_{;t} + g^{st}(\delta\xi^r)_{;t} - g^{rs}{}_{,5}(A_\rho\,\delta\xi^\rho)] \\ &\qquad + J^s[-(A_\rho\,\delta\xi^\rho)_{,s} - \varphi_{st}\delta\xi^t]\}\sqrt{-g}\,d\xi \\ &= \int \{[-2Q_{s}{}^{t}{}_{;t} + \varphi_{ts}J^t]\delta\xi^s \\ &\qquad + [-Q_{rs}g^{rs}{}_{,5} - J^s{}_{;s}](A_\rho\,\delta\xi^\rho)\}\sqrt{-g}\,d\xi. \end{aligned}\right\} \tag{18.19}$$

In carrying out the partial integrations involved in the derivation of this equation, we have omitted all the terms which are covariant divergences. The covariant divergence of a p-vector density is a linear combination of *ordinary* derivatives,

$$\mathfrak{V}^s{}_{;s} = \mathfrak{V}^s{}_{,s} - (\varphi_s \mathfrak{V}^s)_{,5}, \tag{18.20}$$

and vanishes, therefore, when it is integrated over a domain on the boundary of which the components $\mathfrak{V}^s$ vanish.

Since the $\delta\xi^\alpha$ in eq. (18.19) are independent of ξ^5, but otherwise arbitrary in the interior of the domain of integration, we conclude that eqs. (18.16) satisfy the identities

$$\left.\begin{aligned} \int_{\xi^5=0}^{S} (2Q_{s\cdot;t}^{t} + \varphi_{ts}J^t)\sqrt{-g}\, d\xi^5 &= 0, \\ \int_{\xi^5=0}^{S} (J^s{}_{;s} + Q_{rs}g^{rs}{}_{,5})\sqrt{-g}\, d\xi^5 &= 0. \end{aligned}\right\} \tag{18.21}$$

As for the form of the expressions J^s and Q_{rs}, Q_{rs} contains the same terms as the field equations of the general theory of relativity, except that all derivatives are replaced by p-derivatives,

$$g_{rs|t} = g_{rs,t} - g_{rs,5}\varphi_t,$$

and so forth; in addition, the Q_{rs} contain terms in which the p-metric is differentiated with respect to ξ^5. The expressions J^s contain the Maxwell term, $\varphi^{rs}{}_{;s}$, and, in addition, terms which are products of p-derivatives by A-derivatives of the g_{rs}. In other words, the world current density does not vanish in this theory.

Differential field equations. There are two objections to the field equations which can be derived from a variational principle. First, these equations are not uniquely determined; any linear combination of the scalars (18.13), multiplied by $\sqrt{-g}$, is suitable as a Lagrangian. Second, the field equations are not pure differential equations.

If the field equations were a set of pure differential equations, they would have to satisfy stronger identities in order to have significant solutions. Actually, there is a set of fourteen differential equations which satisfy four differential identities and one integro-differential identity; moreover, this set is uniquely determined.

Let us consider the fifteen expressions $G_{\rho\sigma}$ which are formed from the contracted five dimensional curvature tensor,

$$G_{\rho\sigma} = R_{\rho\sigma} - \tfrac{1}{2}\gamma_{\rho\sigma}R. \tag{18.22}$$

These fifteen quantities satisfy the five relationships

$$(\sqrt{\gamma}\, G^{\rho\sigma})_{,\sigma} + \sqrt{\gamma}\, G^{\tau\sigma} \begin{Bmatrix} \rho \\ \tau\sigma \end{Bmatrix} = 0. \tag{18.23}$$

If $\sqrt{\gamma} G^{\rho\sigma}$ is denoted by $\mathfrak{G}^{\rho\sigma}$, and if special coördinates are employed, eq. (18.23) takes the form

$$\left.\begin{aligned} \mathfrak{G}^{rs}{}_{,s} + \mathfrak{G}^{r5}{}_{,5} + \mathfrak{G}^{ts} \begin{Bmatrix} r \\ ts \end{Bmatrix} + 2\mathfrak{G}^{t5} \begin{Bmatrix} r \\ t5 \end{Bmatrix} &= 0, \\ \mathfrak{G}^{5s}{}_{,s} + \mathfrak{G}^{ts} \begin{Bmatrix} 5 \\ ts \end{Bmatrix} + 2\mathfrak{G}^{5s} \begin{Bmatrix} 5 \\ 5s \end{Bmatrix} &= -\mathfrak{G}^{55}{}_{,5}, \end{aligned}\right\} \tag{18.24}$$

for the Christoffel symbols $\{ {\alpha \atop 55} \}$ vanish because of eq. (18.8a). We find that the *fourteen* expressions G^{rs}, G^{r5} satisfy four differential identities; in addition, an expression of the first differential order in the G^{rs} and G^{r5} is identically equal to a derivative with respect to ξ^5, and its integral over one period of an A-curve, therefore, vanishes. The fourteen equations

$$\left.\begin{aligned} G^{rs} &= 0, \\ I^s &= G^{s5} + \varphi_t G^{st} = 0, \end{aligned}\right\} \tag{18.25}$$

thus, satisfy the necessary identities. They are also covariant with respect to special coördinate transformations, for G^{rs} and I^s are p-tensors,

$$G^{rs} = \gamma^r_\rho \gamma^s_\sigma G^{\rho\sigma},$$

$$I^s = \gamma^s_\sigma A_\rho G^{\rho\sigma}.$$

A lengthy but straightforward calculation shows that there is no other set of fourteen differential equations of the second order which are covariant with respect to special coördinate transformations and which satisfy identities similar to those of eqs. (18.25). The form of the equations is the same as the form of the equations which are derived from a suitable variational principle, except that all fourteen equations are differential equations. Again the world current density does not vanish.

APPENDIX A

Ponderomotive Theory by Surface Integrals

In Chapter XV the laws of motion of ponderable bodies under the influence of gravitation were obtained from the field equations, more or less by the methods pioneered by A. Einstein, L. Infeld, and B. Hoffmann.[1] Their procedure, by successive approximations, was refined in a number of subsequent papers.[2] It has been presented in a monograph by L. Infeld and J. Plebański.[3] This original approach, usually referred to as the EIH theory, demonstrates that ponderable bodies must move in the gravitational field according to definite laws in order to permit the existence of solutions of the vacuum field equations in the surrounding space.

The same result was obtained by a different route, and independently, by V. A. Fock.[4] Whereas EIH treated the ponderable body as a point mass, Fock worked with an extended body, whose internal equation of state was assumed known. Both approaches are equally suitable for the treatment of planetary systems in celestial mechanics. They lend themselves to the calculation of post-Newtonian effects that can be observed, and even radiative effects.

But considering that the relationship between field equations and ponderomotive laws is fundamental, and unique, to general-relativistic physics, one would like to obtain this connection independently of any approximation procedures. One would like the connection elucidated independently of the choice of coordinates. Finally, one would like to be able to describe those properties of the ponderable masses that influence their motions in an invariant manner; a typical

characteristic of this kind would be "absence of mass multipole moments." The last one of these objectives has not as yet been achieved, but the approaches to be described in this appendix go a long way toward meeting the first two. To this extent, the theory has been greatly improved.

Essentially the new method involves formulating the laws of motion as statements concerning the time dependence of certain two-dimensional closed-surface integrals, which are interpreted as specific characteristics of the particles inside, such as their mass or their linear momentum. The rates of change of these integrals with time are found to equal other closed-surface integrals, whose integrands represent the fluxes of mass density, linear momentum density, and so forth. Whereas the first type of integrals is taken over expressions that are linear in the first derivatives of the metric, the flux expressions are quadratic in the first derivatives of the metric. Both are free of any higher-order derivatives.

There is a close analogy to this procedure in electromagnetic theory. The electric charge inside a closed two-dimensional surface can be represented by an integral on that surface over the electric displacement, $\oint \mathbf{D} \cdot d\mathbf{S}$. If Maxwell's equations (without charge and without current) hold on that surface, the time derivative of the integrand is proportional to the curl of the magnetic field strength; the time derivative of the electric charge is found to vanish, as a precondition that the field equations can be satisfied on the enclosing surface, though nothing has been assumed concerning the interior. Isolated electric charges cannot change their values in the course of time.

Integral relations of this type can be obtained in any theory whose field equations are derivable from a stationary-action principle that satisfies the *principle of general covariance* (cf. p. 159). They are corollaries of *Noether's theorem*, which systematizes most conservation laws of physics. Noether's theorem in turn involves the notion of *invariance group*. That concept will be our point of departure.

Invariance groups. The principle of relativity asserts that the laws of physics take the same form if expressed in terms of the space and time coordinates of any inertial frame of reference. Likewise, the principle of general covariance asserts the formal equivalence of all curvilinear four-dimensional coordinate systems. In both examples a given physical situation may be described in formally different ways, which however have in common that the form of the dynamical laws is the same in all of them. The transition from one description

to another is governed by the transformation laws of the physical variables involved.

The importance of the transformation laws lies in the circumstance that an inertial frame of reference in the first example, or a curvilinear coordinate system in the second, cannot be identified as such, but only its relationship to other frames, or to other coordinate systems. It is the nature of these relationships that distinguishes special relativity from Newtonian-Galilean physics. In the latter theory two inertial frames of reference are related to each other by a Galilean transformation, such as Eqs. (1.3) on p. 5, whereas in special relativity they will be connected with each other by a Lorentz (or Poincaré) transformation. Whatever the physical theory of concern, the transformations that interconnect the equivalent descriptions, and with respect to which the physical laws remain formally unchanged, are referred to as *invariance transformations*. Galilean transformations in Newtonian mechanics, Lorentz (or Poincaré) transformations in special relativity, curvilinear transformations in general relativity, and gauge transformations in electrodynamics are all invariance transformations.

Generally, invariance transformations form a *transformation group*. We call a set of transformations a transformation group if it satisfies these requirements:

1. If two transformations belonging to the set are performed one after the other, the resulting transformation (called their *product*) also belongs to the set;
2. The identity transformation belongs to the set; and
3. Together with every transformation in the set, its inverse belongs to the set.

The notion of product of two transformations is borrowed from algebra. If two transformations are denoted by the symbols A and B, the symbol BA usually indicates that the transformation A is performed first, B afterwards. (This convention may be assumed to be obeyed in any paper or book whose author does not expressly adopt the opposite convention.) In general, AB and BA are different transformations. If $AB = BA$, then B and A are said to *commute* with each other. If all members of a transformation group commute with each other, the group is called *commutative* or *Abelian*. Except for the group of gauge transformations, none of the transformation groups mentioned in this section are commutative; even two ordinary spatial rotations do not commute with each other unless they are rotations about the same axis.

All the transformation groups that we shall consider are *continuous*. In addition to satisfying the algebraic requirements above, they permit the construction of one-parametric sets of transformations that depend on one parameter, λ, so that in the equation

$$\bar{\xi}^{\mu} = f^{\mu}(\xi^{\rho}, \lambda) \tag{A.1}$$

the derivative $(\partial\bar{\xi}^{\mu}/\partial\lambda)$ exists. For the spatial rotations, for instance, consider rotations about a fixed axis, with the parameter λ standing for the angle through which one rotates. For Lorentz transformations, λ might denote the relative velocity of two Lorentz frames, with the direction of that velocity held fixed.

Consider now one-parametric subsets of a transformation group that include the identity transformation for $\lambda = 0$. The functions

$$\left.\frac{\partial\bar{\xi}^{\mu}}{\partial\lambda}\right|_{\lambda=0} \equiv \delta\xi^{\mu}(\xi^{\rho}) \tag{A.2}$$

are then called *infinitesimal transformations*. Two different one-parametric sets may lead to the same infinitesimal transformation. All infinitesimal transformations together form the *infinitesimal transformation group*, which is a much simpler structure than the (finite) transformation group. It contains much of the structural information on the original group. The members of the infinitesimal transformation group possess two kinds of composition. They are called, respectively, *linear combination* and *commutation*. Both correspond to specific operations within the finite group.

Consider two one-parametric sets of transformations within the group, $A(\lambda)$ and $B(\lambda)$. From them we can form a third one-parametric set, $C(\lambda)$,

$$C(\lambda) = B(\beta\lambda)A(\alpha\lambda)\,. \tag{A.3}$$

α and β denote two arbitrary real nonvanishing numbers. If we denote the corresponding infinitesimal transformations by a, b, and c, respectively, we find the interrelation

$$c = \alpha a + \beta b \tag{A.4}$$

between them. Hence c is a linear combination of a and b.

This relationship can be visualized in terms of the underlying coordinate transformations if these transformations are interpreted as mappings. For a fixed point, Eq. $(A.1)$ represents a one-parametric set of coordinate assignments, or alternatively, a one-parametric set of possible maps, which together form a curve passing through the point ξ^{ρ}. This curve is parametrized by λ, and $\delta\xi^{\mu}$ is a

vector tangent to the curve at the point ξ^ρ. Thus, the infinitesimal transformation a gives rise to a vector at each world point, or a *vector field*. Likewise, b represents a different vector field, and so does c. The coefficients α, β are arbitrary, but constant; they cannot change from point to point.

Consider again the two sets A and B. If A and B do not commute, i.e., if $AB \neq BA$, then AB multiplied by the inverse of BA, denoted by $(BA)^{-1}$, is not the identity transformation. The product $AB(BA)^{-1}$ is known as the *commutator* of A and B. Its infinitesimal analog can, for instance, be obtained by forming the infinitesimal transformation corresponding to the commutator of $A(\sqrt{\lambda})$ and $B(\sqrt{\lambda})$. If the two vector fields corresponding to a and b are denoted by $\delta_a\xi^\mu$ and $\delta_b\xi^\mu$, respectively, then the vector field belonging to the commutator is given by the expression:

$$u^\mu = (\delta_a\xi^\mu)_{,\rho}\,\delta_b\xi^\rho - (\delta_b\xi^\mu)_{,\rho}\,\delta_a\xi^\rho. \tag{A.5}$$

This expression is also known as the *Lie derivative* of the vector field $\delta_a\xi^\mu$ with respect to the field $\delta_b\xi^\mu$. In terms of the infinitesimal transformations themselves, the relationship between a, b, and their commutator u is often symbolized by a so-called commutator bracket,

$$u = [a, b] \equiv -[b, a]. \tag{A.6}$$

Commutator brackets satisfy the *Jacobi identities*,

$$[[a, b], c] + [[b, c], a] + [[c, a], b] \equiv 0. \tag{A.7}$$

Why is one concerned with the structure of transformation groups, rather than merely with statements concerning equivalent frames, and with transformations leading from one to another? Given a physical theory, with its dynamical variables, there are transformation laws not only for the space-time coordinates but also for the dynamical variables, which may be vectors, tensors, affine connections, and even more exotic objects. Suppose that three transformations belonging to the invariance group have the property $ABC = 1$ (where "1" stands for the identity transformation). Then the transformation laws for the variables occurring in the theory must be such that if we apply to any particular choice of the values of the variables first the transformation engendered by C, then the one corresponding to B, and finally the one belonging to A, we must recover the original values. That is to say, any proposed transformation law for field variables or other relevant quantities must reflect the algebraic properties of the invariance group.

The concept of transformation group is not confined to transforma-

tions of coordinates. Gauge transformations of the electromagnetic potentials, discussed in Chapter VII, p. 115, form a transformation group, in that two sets of transformations of the type (7.27), one performed after the other, together are a transformation of the same type. Here the sequence of transformations is immaterial, and the gauge group is commutative. The gauge group is an invariance group: if a set of electrodynamical potential fields satisfies Maxwell's equations, then any new set obtained from the original potentials by a gauge transformation will again satisfy these laws. As the field intensities are unaffected by the gauge transformation, two sets of potentials obtained from each other by a gauge transformation are considered to describe the same electromagnetic field.

In analytical mechanics the point-to-point transformations of generalized coordinates q_k spanning configuration space also form a group. Most of these transformations change the form of the Lagrangian as a function of its arguments q_k, $\dot{q}_k$ (and possibly t). Those that do not are called *invariant transformations*. They form a group by themselves, a *subgroup* of the point-to-point transformations. (The invariant transformations are a subset of the point-to-point transformations, as well as a group in their own right.)

Similarly the canonical transformations in phase space form a group. Among them those canonical transformations that leave unchanged the form of the Hamiltonian as a function of its arguments, $H(q_k, p_k, t)$, again called invariant transformations, form a subgroup. The invariant canonical transformations include the invariant transformations that are point-to-point in configuration space; thus the latter are a subgroup of the former. The invariant canonical transformations are used in one of the formulations of Noether's theorem.

Noether's theorem. In classical mechanics Noether's theorem relates the invariant transformations to the constants of the motion. When applied to field theories it connects the invariant transformations to equations of continuity, which in turn result in certain integrals being constants of the motion. We shall obtain the theorem first within Hamilton's canonical formalism.

Hamilton's equations of motion may be obtained from a variational problem formulated in phase space:

$$\delta S = 0, \qquad S = \int_{t_1}^{t_2} \left(\sum_k p_k \dot{q}_k - H \right) dt. \tag{A.8}$$

The Hamiltonian H is a given function of the canonical coordinates

q_k, p_k (and possibly of the time t), which incorporates the assumed dynamical law of the mechanical system. We shall now consider an infinitesimal transformation of the canonical coordinates, to be denoted by the symbols δq_k, δp_k, and simultaneously a change in the functional dependence of H on its arguments, to be denoted by $\bar{\delta} H$,

$$\bar{\delta} H = \delta H - \sum_k \left(\frac{\partial H}{\partial q_k} \delta q_k + \frac{\partial H}{\partial p_k} \delta p_k \right). \tag{A.9}$$

$\bar{\delta} H$ stands for the change in value of H at a fixed point of phase space. The resulting change in the form of the action integral will be:

$$\bar{\delta} S = \int_{t_1}^{t_2} \left[\sum_k (\dot{p}_k \delta q_k - \dot{q}_k \delta p_k) - \bar{\delta} H \right] dt - \left[\sum_k p_k \delta q_k \right]_{t_1}^{t_2}. \tag{A.10}$$

The change in its value will equal the integral over $-\bar{\delta} H$ from t_1 to t_2.

The extremal curves corresponding to the altered action will be identical with those belonging to the original action if the change of value depends only on the end points,

$$\bar{\delta} S = -\int_{t_1}^{t_2} \bar{\delta} H \, dt = Q_2 - Q_1, \qquad \bar{\delta} H = -\frac{dQ}{dt}, \tag{A.11}$$

where Q is to be some function of the canonical coordinates and the time. If this expression for $\bar{\delta} H$ is substituted into Eq. (A.9), and the latter into Eq. (A.10), the resulting change in the form of the action integral will be:

$$\begin{aligned} \bar{\delta} S = \int \Bigg[& \sum_k \dot{p}_k \left(\delta q_k - \frac{\partial C}{\partial p_k} \right) - \sum_k \dot{q}_k \left(\delta p_k + \frac{\partial C}{\partial q_k} \right) \\ & + \sum_k \left(\frac{\partial H}{\partial q_k} \delta q_k + \frac{\partial H}{\partial p_k} \delta p_k \right) - \frac{\partial C}{\partial t} \Bigg] dt, \qquad (A.12) \\ C \equiv & \sum_k p_k \delta q_k - Q. \end{aligned}$$

The new equations of motion will again be Hamiltonian if the coefficients of $\dot{q}_k$ and of $\dot{p}_k$ vanish (and that means that the infinitesimal coordinate transformation is canonical, and generated by C). The change in the dependence of the Hamiltonian on its arguments will then be given by the expression:

$$\bar{\delta} H = \frac{\partial C}{\partial t} + [C, H] \equiv \frac{dC}{dt}. \tag{A.13}$$

The symbol [,] denotes the Poisson bracket. The right-hand side equals the time rate of change in the value of C along a trajectory obeying Hamilton's equations of motion.

The infinitesimal canonical transformation generated by C will leave the form of the Hamiltonian unchanged—it will be an *infinitesimal invariant transformation*—if (dC/dt) vanishes, that is to say, if C is a *constant of the motion*. This is one form of Noether's theorem, the one adapted to the Hamiltonian formulation of classical mechanics. The theorem may be employed in either direction. Given some invariant transformations, one can construct the generating constants of the motion. Conversely, if one knows a constant of the motion, one can obtain the corresponding infinitesimal invariant transformation.

In the Lagrangian formalism (in configuration space) one may derive Noether's theorem by examining the change in the form of the Lagrangian as a function of its arguments q_k, $\dot{q}_k$, t resulting from an infinitesimal change $\delta q_k(q, \dot{q}, t)$. Permitting again the addition to the Lagrangian of an appropriate exact time derivative, $\dot{Q}$, one finds:

$$\begin{aligned} \delta L &= -\sum_k \delta q_k \left[\frac{\partial L}{\partial q_k} - \frac{d}{dt}\left(\frac{\partial L}{\partial \dot{q}_k}\right)\right] - \frac{dC}{dt}, \\ C &\equiv \sum_k \frac{\partial L}{\partial \dot{q}_k}\,\delta q_k - Q. \end{aligned} \tag{A.14}$$

L will retain its form only if the generator C and the infinitesimal changes in the configuration variables, δq_k, are adjusted to each other so that the time derivative of C along a trajectory equals identically the linear combination of Lagrangian equations of motion that are indicated in Eq. $(A.14)$. If it does, then the time derivative of C vanishes along a trajectory that obeys the equations of motion; C is a constant of the motion.

There are some applications of Noether's theorem to specific dynamical systems, in which all invariant transformations are related to all constants of the motion. More commonly the theorem is exploited with respect to an invariance group, that is to say a group of transformations with respect to which a whole class of dynamical interactions is invariant. For instance, all special-relativistic theories have in common their invariance with respect to the Poincaré group, the transformation group that consists of Lorentz transformations, and rigid displacements. With respect to this group, the relevant constants of the motion are the (total) linear momentum,

which generates spatial displacements, the (total) mass/energy, which generates a displacement along the time axis, the components of the angular momentum, which generate rotations of the three spatial coordinates about spatial axes, and the components of the so-called *boost*, the generators of Lorentz transformations proper, those that involve relative motions of the inertial frames of reference. The three components of the boost are:

$$\mathbf{B} = M\mathbf{X} - t\mathbf{P}. \tag{A.15}$$

M denotes the (total) relativistic mass, $\mathbf{X}$ the coordinates of the center of mass, and $\mathbf{P}$ the (total) linear momentum. The corresponding nonrelativistic constants of the motion, incidentally, generate Galilean transformations.

Next we shall proceed to field theories, where Noether's theorem relates invariant transformations to equations of continuity, of the form Eq. (12.59), p. 194. We shall denote all the components of the field by symbols φ^A, $A = 1, \ldots, N$, where the superscript A is used to number the field components consecutively in some arbitrary manner, which need not be related to their transformation properties. Suppose the field equations are derivable from an action principle of the form

$$\delta S = 0, \qquad S = \int L(\varphi^A, \varphi^A{}_{,\rho})\, d^4x, \tag{A.16}$$

with the usual understanding that the variation extends only over the interior of the domain of integration D. The field equations will have the form:

$$\frac{\delta L}{\delta \varphi^A} \equiv \frac{\partial L}{\partial \varphi^A} - \left(\frac{\partial L}{\partial \varphi^A{}_{,\rho}}\right)_{,\rho} = 0. \tag{A.17}$$

We shall now consider infinitesimal changes in the field variables, $\delta\varphi^A$, with the property that they carry solutions of the field equations over into solutions. They will do so if as a result of the changes contemplated the action will change only by a surface integral,

$$\begin{aligned} \delta S &= \int_D d^4x \left(\frac{\partial L}{\partial \varphi^A}\,\delta\varphi^A + \frac{\partial L}{\partial \varphi^A{}_{,\rho}}\,\delta\varphi^A{}_{,\rho}\right) \equiv \oint Q^\nu\, d^3\Sigma_\nu, \\ d^3\Sigma_\nu &\equiv \delta_{\nu\alpha\beta\gamma} \frac{\partial x^\alpha}{\partial u^1}\frac{\partial x^\beta}{\partial u^2}\frac{\partial x^\gamma}{\partial u^3}\, d^3u. \end{aligned} \tag{A.18}$$

The symbol $\delta_{\nu\alpha\beta\gamma}$ denotes the tensor density of Levi-Civita, defined on p. 60, and the three parameters u^1, u^2, u^3 serve to parametrize the three-dimensional hypersurface that bounds the four-dimensional

domain D. The import of the equality $(A.18)$ is to specify that the change in the value of S does not depend on the values of the field variables φ^A in the interior of the domain D, but only on changes on the bounding hypersurface.

If this condition is satisfied, then the left-hand side of Eq. $(A.18)$ can be transformed by an integration by parts, with the result:

$$\int_D d^4x \frac{\delta L}{\delta \varphi^A} \delta\varphi^A + \oint C^\nu \, d^3\Sigma_\nu \equiv 0, \qquad C^\nu \equiv \frac{\partial L}{\partial \varphi^A{}_{,\nu}} \delta\varphi^A - Q^\nu. \qquad (A.19)$$

The surface integral $\oint C^\nu \, d^3\Sigma_\nu$ will vanish whenever the surface of integration bounds a domain throughout which the field equations $(A.17)$ hold. This is possible only if throughout that domain we have:

$$C^\nu{}_{,\nu} = 0. \qquad (A.20)$$

If the infinitesimal transformation of variables $\delta\varphi^A$ carries all solutions of the field equations into new solutions, then the new Lagrangian density is the same function of its arguments as the original Lagrangian density; $\delta\varphi^A$ is an invariant infinitesimal transformation. C^ν is called the generating density of that transformation, and the three-dimensional integral $\int C^0 \, d^3x$ the generator (or generating integral). With appropriate boundary conditions at the (spatial) edge of the domain of integration, the generating integral is a constant of the motion, thanks to the equation of continuity, $(A.20)$. Just as in mechanics, Noether's theorem relates infinitesimal invariant transformations to conserved quantities.

For what follows it is important to note that Eq. $(A.19)$ does not determine the generating density C^ν uniquely. Choosing an arbitrary field of six components $E^{\rho\sigma} = -E^{\sigma\rho}$, one can construct an alternative generating density D^ν,

$$D^\nu = C^\nu + E^{\nu\sigma}{}_{,\sigma}, \qquad D^\nu{}_{,\nu} \equiv C^\nu{}_{,\nu}, \qquad \oint E^{\nu\sigma}{}_{,\sigma} \, d^3\Sigma_\nu \equiv 0, \qquad (A.21)$$

which will serve as well as the original density C^ν.

If the formulation $(A.19)$, $(A.20)$ of Noether's theorem is to be applied to invariance groups, a distinction must be made between groups whose elements can be identified by a finite number of parameters, which are known as *Lie groups*, and those groups whose elements are identified by arbitrary functions of the four space-time coordinates. The latter are known as *function groups*, or more commonly, in current physicists' usage, as *gauge groups*. The Lorentz and Poincaré groups are examples of Lie groups, whereas

the gauge group of electrodynamics and the group of curvilinear coordinate transformations of general relativity are gauge groups.

If a transformation belongs to a Lie group, and hence is determined throughout space-time once a finite number of parameters have been fixed, then that transformation will in general be nonidentity both in the interior and on the boundary of the chosen domain of integration D. If the transformation forms part of a gauge group, i.e., if it involves an arbitrary function, it is possible to make it the identity on the boundary of D though it is nonidentity in the interior. This distinction between Lie groups and function groups has significant implications for the structure of the generators.

Consider once more the identity (A.19), but on the assumption that the invariant transformation belongs to a gauge group, and that it has been chosen so that it represents the identity transformation on the bounding surface, including a sufficient (finite) number of derivatives out of the surface. As the generating density C^ν, or D^ν of Eq. (A.21), depends only on the properties of the transformation on the surface, a possible choice of the generating density is to make it vanish on that surface. Hence the linear combination of field equations implied by the first term of the identity (A.19) will have an identically vanishing volume integral if δy_A and its off-surface derivatives vanish on the bounding surface. Thus the existence of identities between the field equations and the vanishing of the generators of invariant transformations that form function groups are two results having a common root.

Einstein's vacuum field equations will serve to illustrate both. The action integral is given by Eq. (12.43), p. 190, and its variation under arbitrary variations of the metric by Eq. (12.54). In terms of the variation of the covariant metric (which is slightly more convenient for what follows), this expression may be turned into:

$$\delta \int \sqrt{-g}\, R\, d^4\xi \equiv -\int d^4\xi \sqrt{-g}\, G^{\mu\nu}\delta g_{\mu\nu} + \oint Q^\nu\, d^3\Sigma_\nu . \quad (A.22)$$

The last term on the right contains the remainder of integrations by part. If we wish to examine the change in action that is brought about by an infinitesimal coordinate transformation, the change in the metric as a function of the coordinates will be:

$$\delta_f g_{\mu\nu} = -(g_{\mu\rho} f^\rho{}_{,\nu} + g_{\nu\rho} f^\rho{}_{,\mu} + g_{\mu\nu,\rho} f^\rho) \equiv -(f_{\mu;\nu} + f_{\nu;\mu}) . \quad (A.23)$$

The symbol f^ρ stands for the infinitesimal change in the coordinate values of a given world point

$$f^\rho \equiv \delta\xi^\rho . \quad (A.24)$$

$f^\rho(\xi)$ forms an (arbitrary) vector field. The left-hand side of Eq. $(A.22)$ is an integral over a scalar density. Its value will change only because of the (infinitesimal) shift in the boundary of the domain of integration, and this change can be represented as an integral over that bounding surface. With these substitutions made, Eq. $(A.22)$ takes the form:

$$\int d^4\xi\sqrt{-g}\, G^{\mu\nu}(f_{\mu;\nu} + f_{\nu;\mu}) + \oint (Q^\nu + \sqrt{-g}\, Rf^\nu)\, d^3\Sigma_\nu \equiv 0\,. \qquad (A.25)$$

This identity has now precisely the form $(A.19)$. It remains to establish the precise form of the integrand of the surface integral, that is to say, the generating density. One may trace in detail the form of Q^ν resulting from the several integrations by part. But it is more convenient to start directly from the first term of Eq. $(A.25)$, using the contracted Bianchi identities. We have:

$$\begin{aligned}\int d^4\xi\sqrt{-g}\, G^{\mu\nu}(f_{\mu;\nu} + f_{\nu;\mu}) \\ &\equiv 2\int d^4\xi\sqrt{-g}\, G^{\mu\nu}f_{\mu;\nu} \equiv 2\int d^4\xi(\sqrt{-g}\, G^\nu{}_\mu f^\mu)_{;\nu} \qquad (A.26)\\ &\equiv 2\oint \sqrt{-g}\, G^\nu{}_\mu f^\mu\, d^3\Sigma_\nu\,.\end{aligned}$$

Hence the generating density of an infinitesimal coordinate transformation is:

$$C^\nu = -2\sqrt{-g}\, G^\nu{}_\mu f^\mu\,. \qquad (A.27)$$

This vector field does indeed satisfy an equation of continuity when the vacuum field equations are satisfied, in spite of the appearance of the arbitrary functions f^μ. It accomplishes this feat by vanishing altogether, a somewhat disappointing result.

The expression $(A.27)$ as a generating density suffers from the further drawback that it involves second-order derivatives of the field variables, the components of the metric tensor. Both disadvantages can be eliminated by the addition of a term of the type $(A.21)$. However, the resulting generating density D^ν is no longer a vector density, like C^ν. The appropriate choice of $E^{\nu\rho}$ is[5]:

$$E^{\nu\rho} = U^{\nu\rho}{}_\tau f^\tau, \qquad U^{\nu\rho}{}_\tau = \mathfrak{g}_{\tau\beta}(\mathfrak{g}^{\nu\alpha}\mathfrak{g}^{\rho\beta} - \mathfrak{g}^{\nu\beta}\mathfrak{g}^{\rho\alpha})_{,\alpha}\,. \qquad (A.28)$$

[5] Ph. Freud, *Ann. Math.*, **40**, 417 (1939). L. Landau and E. Lifshitz, *The Classical Theory of Fields* (English translation), p. 317 f. Addison-Wesley, Reading, Mass., 1951.

The symbols $\mathfrak{g}^{\mu\nu}$, $\mathfrak{g}_{\mu\nu}$ are short for

$$\mathfrak{g}^{\mu\nu} \equiv \sqrt{-g}\, g^{\mu\nu}, \qquad \mathfrak{g}_{\mu\nu} = (-g)^{-1/2} g_{\mu\nu}. \tag{A.29}$$

The new generating density D^ν, Eq. (A.21), is quadratic in first-order derivatives of the metric, free of second-order derivatives, and non-zero. It satisfies an equation of continuity (i.e., its divergence vanishes) wherever the vacuum field equations hold.

The surface integral theorems. For general relativity the generating density D^ν in vacuum has the value

$$D^\nu = (U^{\nu\rho}{}_\tau f^\tau)_{,\rho}, \tag{A.30}$$

in view of the fact that C^ν vanishes. If the vacuum field equations hold in a four-dimensional domain, then the integral of D^ν over the bounding three-dimensional hypersurface must vanish,

$$\oint D^\nu\, d^3\Sigma_\nu = 0. \tag{A.31}$$

It follows in particular that if two three-dimensional domains have their two-dimensional boundaries in common, and if one of them can be carried over into the other by continuous deformation, sweeping out in the process a four-dimensional domain throughout which the vacuum equations are satisfied, then the two three-dimensional integrals must have the same value:

$$\int_{\mathrm{I}} D^\nu\, d^3\Sigma_\nu = \int_{\mathrm{II}} D^\nu\, d^3\Sigma_\nu. \tag{A.32}$$

Hence this value is determined by the common boundary; indeed, in view of Eq. (A.30), and applying the generalized Stokes' theorem, we must have:

$$\int D^\nu\, d^3\Sigma_\nu = \tfrac{1}{2} \oint U^{\nu\rho}{}_\tau f^\tau\, d^2\Sigma_{\nu\rho}. \tag{A.33}$$

This relation would be trivial if we were to use for D^ν the expression (A.30), but it is not if D^ν stands for (A.21), with C^ν given by Eq. (A.27) and $E^{\nu\rho}$ by Eq. (A.28). The integrand on the right of Eq. (A.33) is linear in the first-order derivatives of the metric, whereas the integrand on the left is quadratic in first-order derivatives, and free of second-order derivatives; the relationship holds only if the vacuum field equations are satisfied everywhere on the three-dimensional domain of integration of the left-hand side.

It is to be noted that theorems of the kind (A.33) can be obtained for any physical theory whose dynamical laws are derivable from an action principle that is form-invariant with respect to curvilinear

coordinate transformations. For instance, if Einstein's action principle is augmented by a Maxwell-Lorentz term, so as to couple the gravitational field to the electromagnetic field, then the "vacuum" field equations will hold away from ponderable and electrically charged matter (but in the presence of electromagnetic as well as gravitational fields). Hence there will be an integral theorem of the general form (A.33), with the integrands on both sides containing additional terms involving the electromagnetic field. On the left, the field intensities will enter quadratically, on the right only linearly, but multiplied by undifferentiated potentials.[6]

Ponderomotive laws. Consider a number of discrete sources giving rise to a gravitational field. That is to say, each of the sources at any given time can be enclosed in a separate sphere-like two-dimensional surface. In space-time the enclosure of each source will be a three-dimensional tube, extending indefinitely in a time-like direction.

One such tube may now be surrounded by a three-dimensional hypersurface that lies everywhere in vacuum. Of course, this

Fig. 10. The slender long tube encloses a source of the field. It is surrounded by a three-dimensional surface that intersects the source region nowhere and which is bounded by two disjoint two-dimensional domains.

[6] Expressions involving both electromagnetic fields and the scalar field, that has been conjectured, e.g., by R. H. Dicke, are to be found in P. G. Bergmann, *Intl. J. Theoret. Physics*, **1**, 25 (1968).

hypersurface Σ^3 (Fig. 10) is not the boundary of a four-dimensional domain. On the contrary, it has a two-dimensional boundary of its own, which consists of two disjoint pieces, each of which resembles the surface of an ordinary sphere (S^2 in standard topological notation). The equality (A.33) may be properly applied to Σ^3 and its boundary (II − I), as the vacuum conditions hold everywhere on it. It may be written in the form

$$\tfrac{1}{2}\oint_{\mathrm{II}} E^{\nu\rho}\, d^2\Sigma_{\nu\rho} - \tfrac{1}{2}\oint_{\mathrm{I}} E^{\nu\rho}\, d^2\Sigma_{\nu\rho} = \int_{\Sigma^3} D^\nu\, d^3\Sigma_\nu\,. \qquad (A.34)$$

This is to say, the two-dimensional integrals taken over II and I, respectively (both being surfaces enclosing the same source) differ by an amount that is determined by the total flux passing through that enclosing surface between the two "instants" I and II. Hence an integral taken over one enclosing two-dimensional surface, I or II, measures something that is conserved, in the sense that in ordinary field theories energy density, linear momentum density, or angular momentum density are conserved.

If the two-dimensional surfaces of integration in the relationship (A.34) are chosen to be coordinate hypersurfaces, e.g., ξ^0 = constant, and if they are infinitesimally close to each other, then one can infer the differential relation:

$$\frac{\partial}{\partial\xi^0}\oint E^n\, dS_n = \oint D^n\, dS_n\,, \qquad dS_n \equiv \tfrac{1}{2}\delta_{nkl}\, d^2\Sigma^{kl}, \qquad \text{etc.} \qquad (A.35)$$

The "time" derivative of one surface integral equals another surface integral.

Both integral equalities (A.34) and (A.35) involve fields of the four arbitrary functions f^τ. In principle, then, each of these relations is equivalent to an infinity of relations, which differ by the choice of f^τ. To interpret them is a challenging task, which has not been entirely completed. The discussion that follows will be concerned principally with the formulation (A.34).

Equations (A.34) are equivalent to the claim that

$$\int_{\Sigma^3} \sqrt{-g}\, G^\nu{}_\tau f^\tau\, d^3\Sigma_\nu = 0\,. \qquad (A.36)$$

This formulation facilitates the transition from one coordinate system to another. Assuming that the domain of integration is fixed independently of the choice of coordinates, the arbitrary functions f^τ must be transformed as a contravariant vector field in order to obtain in a

new coordinate system the statement equivalent to the original assertion. Of course, only the totality of statements of the form (A.36), with a complete set of fields f^τ on the domain of integration, leaving out no linearly independent vector field, exhausts the simple assertion that on the domain Σ^3 the vacuum field equations are satisfied everywhere. With any particular choice of the field f^τ, Eq. (A.36) merely states that an integral with a certain weighting of the vacuum field equations vanishes. At any rate, the import of any chosen set of equations (A.36) in one coordinate frame can be matched by an equivalent set of statements in any other coordinate system. The domain of integration must be the same in both frames; it cannot be "dragged along" by the coordinate transformation.

The next natural step in the interpretation of the integral formulas would seem to involve a search for the physical significance of the two-dimensional surface integrals appearing on the left of Eq. (A.34). But their integrand lacks any intrinsic meaning. Superficially, that integrand resembles that of the charge integral in electrodynamics,

$$Q = \frac{1}{4\pi} \oint \mathbf{D} \cdot \mathbf{dS}, \qquad (A.37)$$

in that it involves the first derivatives of the (gravitational) potentials linearly. But whereas the electric displacement $\mathbf{D}$ forms part of a contravariant skew-symmetric tensor density (which moreover is gauge-invariant), so that $\mathbf{D} \cdot \mathbf{dS}$ is a scalar, the expression $E^{\mu\nu}$, Eq. (A.28), behaves like a tensor density only with respect to linear coordinate transformations; these have no special significance in general relativity. Indeed, by a suitable choice of coordinates one can make the components of $E^{\mu\nu}$ vanish at any one world point, simply by reducing the Christoffel symbols (and with them the first derivatives of $g_{\mu\nu}$) there to zero. Of course, if the curvature tensor does not vanish at that point, the second-order derivatives of the metric will be non-zero.

A few surface integrals $\frac{1}{2} \oint E^{\mu\nu}\, d^2\Sigma_{\mu\nu}$ are invariant in the linearized weak-field approximation, which was discussed in Chapter XII, on pp. 180 ff. First it is to be remarked that the expression D^ν, Eq. (A.21), with C^ν substituted from Eq. (A.27) and $E^{\mu\nu}$ from Eq. (A.28), consists of terms in which f^τ occurs undifferentiated and terms in which f^τ is differentiated once. The first set of terms contains the Christoffel symbols quadratically; the second is linear in the Christoffel symbols. If one restricts oneself to f^τ that are constant in the chosen coordinate system, then only the terms of the first kind are

non-zero, and these are proportional to the so-called canonical energy-momentum complex originally proposed by Einstein, the expression $\sqrt{-g}\, t^{\mu}{}_{\tau}$ introduced in Eq. (12.68). A three-dimensional integral of the form $\int \sqrt{-g}\, t^{\mu}{}_{\tau}\, d^3\Sigma_{\mu}$ generates an infinitesimal rigid displacement of the coordinate system along the ξ^{τ}-axis.

With the restriction to constant f^{τ} in mind, we now go over to the linearized approximation. In this approximation the energy-momentum complex vanishes (because it is homogeneous-quadratic in the Christoffel symbols). Outside the sources of the gravitational field it equals a divergence, Eq. (A.30), hence the transformation law of $E^{\mu\nu}$ must preserve its divergence-free character. Indeed, in the linearized approximation we find:

$$\begin{aligned} E^{\mu\nu *} &= E^{\mu\nu} + (v^{\mu\nu} f^{\rho} + v^{\nu\rho} f^{\mu} + v^{\rho\mu} f^{\nu})_{,\rho}, \\ v^{\mu\nu} &\equiv v^{\mu}{}_{,\sigma}\, e^{\sigma\nu} - v^{\nu}{}_{,\sigma}\, e^{\sigma\mu}, \end{aligned} \tag{A.38}$$

always provided f^{τ} is constant and unchanged by the coordinate transformation. The integral of such an expression taken over a closed two-dimensional domain vanishes identically, on account of Stokes' theorem (in the form appropriate to four-dimensional geometry). Hence the integral of $E^{\mu\nu}$ itself is invariant with respect to transformations of the type (12.21).

To accord this integral some physical significance, we shall return once more to its being equal to a three-dimensional volume integral extended over the volume enclosed by the surface S^2. In Fig. 10 this would be a space-like domain cutting across the tube containing the source, not the time-like surface Σ^3. As this latter integral is the generator of a rigid infinitesimal coordinate displacement, it is tempting to adopt the interpretation common to Newtonian and Lorentz-covariant physical theories, to the effect that the generators of rigid displacements are the total energy and the total linear momentum. This is indeed what is done. The choice $f^{\tau} = \delta^{\tau}{}_{0}$ results in the expression for the (relativistic) mass/energy. To adapt the domain of integration to a slice $\xi^0 =$ constant, one must give the two superscripts μ, ν the values of 0 and n ($n = 1, 2, 3$), respectively. The integrand E^{0n} then becomes:

$$E^{0n} = \gamma_{00,n} - \gamma_{n\alpha,\alpha}\,. \tag{A.39}$$

One can always construct a coordinate frame in which the second term vanishes over the whole domain of integration, and one is left with an integral of the first term, which is the gradient of the Newtonian gravitational potential. This integral represents the

gravitating mass in the interior of the surface of integration, S^2. Thus, in spite of the approximation used, this formalism retains the principle of equivalence of gravitating mass and energy characteristic of the general theory of relativity.

These results look encouraging, but they cannot be extended beyond the realm of the linearized approximation. No corresponding invariant surface integrals have been discovered in the full theory, and this is no accident. When nonlinear terms are taken into consideration, the whole gravitational field inside a two-dimensional surface contributes to the energy, and it is well known that this field energy has no invariant meaning.

In the linearized theory translations and Lorentz transformations play a special role; they are the transformations that preserve the form of the zeroth-order metric (also referred to as the background metric). They lose this special significance in the full theory and are submerged in the group of curvilinear transformations. One may reasonably expect that likewise the generators of translations and Lorentz transformations have no outstanding significance among the generators of arbitrary coordinate transformations. In physical situations in which the metric is asymptotically flat at infinity there is the class of coordinate systems adapted to these boundary conditions, and with it the group of coordinate transformations preserving them. Their generators (i.e., total energy, total linear momentum, etc.) have intrinsic meaning, but not their local generating densities. Hence these properties cannot be attributed to individual particles in the presence of additional sources of the gravitational field.

If it is difficult to define the mass of a particle in the presence of an incident gravitational field in a satisfactory manner, this difficulty is compounded when it comes to such parameters as the dipole moment, the angular momentum (i.e., the spin), the mass quadrupole moment, and so forth. But from the analogy to Lorentz-covariant theories of physics we know that all of these parameters affect the motion of the particle. If we include at least terms quadratic in the Christoffel symbols in a weak-field approximation expansion applied to Eq. (A.35), then there will be nontrivial terms on the right-hand side of that dynamical equation. Suppose we expand, at any stage of the weak-field approximation, the Christoffel symbols in powers of r, the (Cartesian) distance from the particle's center, then we shall have both negative and positive powers. Somewhat rhetorically, the terms with negative powers of r might be said to belong to the "self-field" of the particle, those with positive powers to the "incident field." Those products of Christoffel symbols will be independent of

the "radius" of the sphere of integration in which one factor will have a positive power n, the other a negative power $-(n + 2)$. For instance, the gradient of the Newtonian potential $-M/r$ will drop off with the second negative power of r, and it will be multiplied by the r^0 term of the ambient field, its value at the location of the particle itself.

In like fashion, the self-field associated with the particle's spin will be multiplied by the first derivative of the incident gravitational field strength, and so forth. All these terms will contribute to the rate of change of the particle's energy or linear momentum on the left-hand side of Eq. (A.35). At the higher-order stages of the weak-field approximation neither the left nor the right of Eq. (A.35) are invariant, or covariant, so no logical inconsistency arises. But there remains a paradox, which continues to beset the foundations of the theory of motion.

In spite of the remaining conceptual difficulties, the theory of motion has been applied with complete success to the so-called post-Newtonian effects in celestial mechanics, and also to the evaluation of the radiative reaction associated with accelerated ponderable bodies. On balance, general relativity has contributed significantly to our understanding of the relationship between field equations and the motions of the field's sources.

THE COSMOLOGICAL INFLUENCE ON MATTER (COSMIC OBJECTS, DARK MATTER AND PARTICLES) PREDICTED BY THE 5-DIMENSIONAL PROJECTIVE UNIFIED FIELD THEORY

E. SCHMUTZER
University of Jena, Germany

Abstract. The last version of the Projective Unified Field Theory of the author (non-Einstein-like 5-dimensional field equations, but original projection formalism) overcomes the physical difficulties of the former variants (equivalence principle, equation of motion, spinor theory etc.). This version has been applied to cosmology and cosmogony in a series of publications. Some main results are: 1. Closed homogeneous isotropic cosmological model without big bang, exhibiting satisfying values for the age of the cosmos [19 billion years], Hubble factor H [67.8 km/(s Mpc)], relative temporal change of the effective gravitational constant [$1.58 \cdot 10^{-11}$/year] etc. 2. Dominating repulsion interaction between the cosmic particles in the first stage after the "big start" (instead of big bang). 3. Decreasing radius and decreasing excentricity of circle-like orbiting bodies moving about a center etc. 4. Heat production ("bremsheat") within a moving body, induced by the cosmological expansion and being possibly interesting with respect to seismic and volcanic activities of celestial bodies. 5. Bremsheat induced expansion of celestial bodies with realistic expansion velocities (Earth: $6.8 \cdot 10^{-2}$ cm/year; Sun: 0.39 cm/year). 6. Accretion theory of dark matter around a center with a possible explanation of the "Pioneer effect" of satellites. 7. Theory of the "rotation curves" of orbiting stars in galaxies. 8. The new concept of mass partly fulfills Mach's principle.

1. Retrospect

My education in differential geometry was based on the compact vector calculus. Therefore in my axiomatics of the geometry of the 5-dimensional projective space I took the basis vectors (spanning the space) as the genuine carriers of information on curvature, torsion etc. The further historical research on differential geometry went another way by introducing the concept of the "external differential calculus" into geometry and particularly into geometrized field theories. It

P.G. Bergmann and V. de Sabbata (eds.),
Advances in the Interplay Between Quantum and Gravity Physics, 387–433.
© 2002 *Kluwer Academic Publishers.*

was A. Gorbatsievich [1] who recently could prove that my results can fully be reproduced within the framework of this contemporary geometrical language.

The Projective Unified Field Theory (PUFT) has been developed in 3 stages: first versions 1957 and 1980 [2] and final version 1995 [3], which differ by different field equations and projection formalisms for the transition from the 5-dimensional projective space to the 4-dimensional space-time. The last version (non-Einstein-like 5-dimensional field equations, but original projection formalism) overcomes the physical difficulties of the former variants (equivalence principle, equation of motion, spinor theory etc.). This version has been applied to cosmology and cosmogony in a series of publications.

Since my lectures at several Erice Courses on Gravitation and Cosmology were published in the proceedings of these courses [4], I can restrict myself here to the presentation of the last version of the field equations and conservation laws. Therefore the main part of this paper will treat the application of PUFT to cosmology, cosmogony and astrophysics. Work on a detailed monograph started recently, in which the historical development, the mathematical and physical basis of PUFT, the physico-philosophical interpretation and various applications will be presented [5].

Further I would like to mention that in my treatises on PUFT I had to use a special terminology in order to cope with the physically new situation within this theory.

2. Five-dimensional Hamilton principle, field equation and conservation law

Following conventions are used: The geometrical basis of the 5-dimensional projective space (X^μ 5-dimensional homogeneous coordinates) as well as of the 4-dimensional space-time (x^i 4-dimensional curvilinear coordinates) is the Riemannian geometry. Greek indices run from 1 to 5, Latin indices from 1 to 4. Comma and semicolon mean the partial derivative and the covariant derivative, respectively. Further the Gauss system of units (as mostly in astrophysics) is used.

The squared 5-dimensional line element is defined by ($g_{\mu\nu}$ 5-dimensional metric with the signature {+,+,+,+,-})

$$\left(\mathrm{d}\overset{5}{s}\right)^2 = g_{\mu\nu}\mathrm{d}X^\mu\,\mathrm{d}X^\nu\,. \tag{1}$$

In our theory the scalar field S means the length of the 5-dimensional radius vector existing in our geometrical concept. This quantity is in a specific way related to the scalar field of the various Kaluza-Klein theories and the Jordan theory. As it is well known, Jordan was the first who dropped the norm condition (constant scalar field) in the older projective relativity theories [6].

The definition of S results from

$$S^2 = g_{\mu\nu}X^\mu\,X^\nu\,. \tag{2}$$

In our theory it is more appropriate to use the quantity σ which we call for certain definite reasons scalaric field:

$$\sigma = \ln \frac{S}{S_0} \tag{3}$$

(Here S_0 is a basic constant of the physical dimension of length. It does not occur in our papers on cosmology, cosmogony and astrophysics, but it plays a certain role in the theory of spinors).

Starting point of our theory is the 5-dimensional action integral [3]

$$\text{a)} \quad W = \frac{1}{c}\int\limits_{V_5} \overset{5}{L} \mathrm{d}^{(5)} f = \frac{1}{c}\int\limits_{V_5} \overset{5}{\mathcal{L}} \mathrm{d}^{(5)} X \quad \text{with} \quad \text{b)}\ \overset{5}{\mathcal{L}} = \overset{5}{L}\sqrt{\overset{5}{g}} \tag{4}$$

($\overset{5}{L}$ Lagrange density, $\overset{5}{\mathcal{L}}$ Lagrange function, $\overset{5}{g}$ = - $\det(g_{\mu\nu})$ metric determinant, $\mathrm{d}^{(5)} f$ 5-dimensional volume element, c velocity of light in vacuo).

The Hamilton principle

$$\begin{aligned} &\text{a)} \quad \delta \int\limits_{V_5} \overset{5}{\mathcal{L}} \mathrm{d}^{(5)} X = 0 \quad \text{with} \\ &\text{b)} \quad \delta g_{\mu\nu} \Big|_{(V_5)} = 0\,,\ \delta g_{\mu\nu,\tau} \Big|_{(V_5)} = 0 \quad \text{(Hamilton boundary conditions)} \end{aligned} \tag{5}$$

leads to the Lagrange equation

$$\frac{\delta \overset{5}{\mathcal{L}}}{\delta g_{\mu\nu}} = \frac{\partial \overset{5}{\mathcal{L}}}{\partial g_{\mu\nu}} - \left(\frac{\partial \overset{5}{\mathcal{L}}}{\partial g_{\mu\nu,\tau}}\right)_{,\tau} + \left(\frac{\partial \overset{5}{\mathcal{L}}}{\partial g_{\mu\nu,\tau,\sigma}}\right)_{,\tau,\sigma} = 0\,. \tag{6}$$

According to our concept we split the Lagrange density into the geometrizable part (fields $g_{\mu\nu}$ and σ) and the up to now non-geometrizable part named substrate:

$$\overset{5}{L} = \overset{5}{L}_{geom} + \overset{5}{L}_{sub}. \tag{7}$$

The quantities being at our disposal for constructing the geometrized Lagrange density with appropriate transformation properties are the metric $g_{\mu\nu}$ and the scalar field S as well as the derivatives of both quantities. For the following we refer to a second order theory. Nevertheless the variety of construction is enormously large. Let us here repeat our ideas which led us in our paper [3] to a basic selection principle which was used as the fundament of PUFT (version 1995).

We remembered the fascinating property of Dirac's field theory of the electron/positron: The Lagrange density has the well-known form constructed of the bispinor field. With the help of the Hamilton principle the field equation of the

actual motion of the bispinor field is derived. Inserting of the field equation into the Lagrange density leads to the surprising result that the Lagrange density of the actual motion is zero.

We considered this special field-theoretical case as an indication of a deeper founded phenomenon in nature and tried to test tentatively this hypothesis in our unified field theory. Following this idea we started with the ansatz

$$\overset{5}{L}_{geom} = f(S)\overset{5}{R} + g(S)S^{,\alpha}{}_{;\alpha} + h(S)S^{,\alpha}S_{,\alpha} + k(S). \tag{8}$$

In this context it is advisable to introduce the energy projector of the substrate ($\varkappa_0$ Einstein's gravitational constant as a true constant of nature)

$$\Theta^{\mu\nu} = \frac{1}{\varkappa_0 f\sqrt{\overset{5}{g}}}\frac{\delta\overset{5}{\mathcal{L}}_{sub}}{\delta g_{\mu\nu}}\,. \tag{9}$$

If one uses the ansatz (8) for deriving the field equations, one receives a certain result. Inserting this in the Lagrange density leads to the structure of the Lagrange density of the actual motion of the fields

$$\overset{5}{L}_{act} = \overset{5}{L}_{metric,act} + \overset{5}{L}_{sub,act} - \frac{2\varkappa_0 f^2}{3f + Sf'}\Theta^{\mu}_{\mu}\,. \tag{10}$$

Following the line described above, for determining the four free functions f, g, h, k and by further considerations with respect to positive definiteness of the scalaric field energy we demand

$$\overset{5}{L}_{metric,act} = 0\,. \tag{11}$$

Now two possibilities for further restriction appear:

Substrate null principle:

$$\text{a)}\quad \overset{5}{L}_{sub,act} = 0 \quad \text{with} \quad \text{b)}\ \overset{5}{L}_{act} = -\frac{2\varkappa_0 f^2}{3f + Sf'}\Theta^{\mu}_{\mu}\,; \tag{12}$$

Strong null principle:

$$\text{a)}\overset{5}{L}_{sub,act} = \frac{2\varkappa_0 f^2}{3f + Sf'}\Theta^{\mu}_{\mu} \quad \text{with} \quad \text{b)}\ \overset{5}{L}_{act} = 0\,. \tag{13}$$

Our further calculations are based on the "substrate null principle" ("next to nothing principle"). Here it is not possible to go into details.

The 5–dimensional field equation reads:

$$
\begin{aligned}
& R_{\mu\nu} - \frac{1}{2}\overset{5}{R}g_{\mu\nu} - \frac{1}{S}S_{,\mu;\nu} - \frac{2}{S^2}S_{,\mu}S_{,\nu} \\
& -\frac{1}{S}s_\mu s_\nu \left(4S^{,\tau}{}_{;\tau} - \frac{6}{S}S_{,\tau}S^{,\tau} + \frac{3\lambda_0}{S} - \frac{1}{2}\overset{5}{R}S\right) \\
& +\frac{1}{S}g_{\mu\nu}\left(S^{,\tau}{}_{;\tau} + \frac{\lambda_0}{S}\right) = \varkappa_0\Theta_{\mu\nu}
\end{aligned}
\tag{14}
$$

($R_{\mu\nu}$ Ricci tensor, $\overset{5}{R}$ 5-dimensional curvature invariant, $s_\mu = X_\mu/S$ radial unite vector, λ_0 quasi–cosmological constant similar to the cosmological constant of the Einstein theory). From (14) follows the conservation law

$$
\left(\frac{1}{S}\Theta_\mu{}^\nu\right)_{;\nu} = 0\,. \tag{15}
$$

Further we mention the cyclic relation

$$
s_{<\rho\sigma,\tau>} = 0 \tag{16}
$$

being an identity within the framework of the theory of projectors.

Later it becomes obvious that the Einstein theory is the special case $\sigma = const$ of our theory.

3. Four-dimensional field equations and balance equations (conservation laws)

For our further investigations we drop the quasi-cosmological term: $\lambda_0 = 0$. The projection from the 5–dimensional projective space onto the 4–dimensional space–time leads to following sets of equations.

3.1. GENERALIZED GRAVITATIONAL FIELD EQUATIONS

$$
R^{ij} - \frac{1}{2}Rg^{ij} = \varkappa_0 T^{ij} \tag{17}
$$

with the usual meaning of the symbols. The energy tensor

$$
T^{ij} = E^{ij} + S^{ij} + \Theta^{ij} \tag{18}
$$

consists of the following three terms:

$$
\begin{aligned}
&\text{a)} \quad E^{ij} = \frac{1}{4\pi}\left(B^{ik}H_k{}^j + \frac{1}{4}g^{ij}B_{kl}H^{kl}\right), \\
&\text{b)} \quad S^{ij} = \frac{2}{\varkappa_0}\left(\sigma^{,i}\sigma^{,j} - \frac{1}{2}g^{ij}\sigma_{,k}\,\sigma^{,k}\right)
\end{aligned}
\tag{19}
$$

and the substrate energy tensor Θ^{ij} describing the substrate (B_{ij} electromagnetic field strength tensor, H_{ij} electromagnetic induction tensor).

3.2. GENERALIZED ELECTROMAGNETIC FIELD EQUATIONS

$$\text{a)}\quad H^{ij}{}_{;j} = \frac{4\pi}{c} j^i\,, \quad \text{b)}\ B_{\langle ij,k\rangle} = 0\,, \quad \text{c)}\ H_{ij} = e^{2\sigma} B_{ij} \tag{20}$$

(j^i electric current density).

3.3. SCALARIC FIELD EQUATION

$$\sigma^{,j}{}_{;j} = -\frac{\varkappa_0}{2}\left(\vartheta + \frac{1}{8\pi} B_{kl} H^{kl}\right)\,, \tag{21}$$

where

$$\vartheta = \Theta_\mu{}^\mu - \Theta_k{}^k \tag{22}$$

is the scalaric substrate energy density (short: scalerg density). The corresponding scalmass density is defined by

$$\mu^{(\sigma)} = \frac{1}{c^2}\vartheta\,. \tag{23}$$

From the above field equations the following balance equations (conservation laws) result:

$$\text{a)}\quad \Theta_i{}^k{}_{;k} = -\frac{1}{c} B_{ik} j^k + \vartheta\sigma_{,i}\,, \quad \text{b)}\quad j^k{}_{;k} = 0\,. \tag{24}$$

If we consider an electrically charged mechanical continuum (without conductive effects), the substrate energy tensor and the electric current density take the form

$$\text{a)}\quad \Theta_{ij} = -\left(\mu + \frac{p}{c^2}\right) u_i u_j - p g_{ij}\,, \quad \text{b)}\quad j^k = \rho_0 u^k\,, \tag{25}$$

respectively (μ mass density of the substrate, p mechanical pressure, ρ_0 electrical rest charge density, $u^i = \mathrm{d}x^i/\mathrm{d}\tau$ 4-velocity with $u_i u^i = -c^2$, τ proper time). Then from (25) result the mechanical equation of motion

$$\left(\mu + \frac{p}{c^2}\right) u^k{}_{;l} u^l = \frac{1}{c}\rho_0 B^k{}_l u^l - \left(p^{,k} + \frac{1}{c^2}\frac{\mathrm{d}p}{\mathrm{d}\tau} u^k\right) - \vartheta\left(\sigma^{,k} + \frac{1}{c^2}\frac{\mathrm{d}\sigma}{\mathrm{d}\tau} u^k\right) \tag{26}$$

and the mechanical balance equation

$$\left[\left(\mu + \frac{p}{c^2}\right) u^k\right]_{;k} = \frac{1}{c^2}\left(\frac{\mathrm{d}p}{\mathrm{d}\tau} + \vartheta\frac{\mathrm{d}\sigma}{\mathrm{d}\tau}\right)\,. \tag{27}$$

In context with the equivalence principle we postulate

$$\mu = \mu^{(\sigma)}\sigma\,. \tag{28}$$

Then from (27) we obtain

$$\left[\left(\mu^{(\sigma)} + \frac{p}{\sigma c^2}\right) u^k\right]_{;k} = \frac{1}{c^2}\frac{\mathrm{d}}{\mathrm{d}\tau}\left(\frac{p}{\sigma}\right)\,. \tag{29}$$

The transition from (26) to a point-like test body by spatial integration leads to the equation of motion

$$M u^k{}_{;l} u^l = \frac{Q}{c} B^k{}_l u^l - D\left(\sigma^{,k} + \frac{1}{c^2}\frac{\mathrm{d}\sigma}{\mathrm{d}\tau} u^k\right)\,. \tag{30}$$

Here mean: M inertial mass (including pressure), Q electric charge, D scalerg of the test body corresponding to the scalerg density (22). Furthermore, the scalmass $\mathcal{M}$ of the body corresponding to the scalmass density (23) is given by

$$\mathcal{M} = \frac{D}{c^2}\,, \tag{31}$$

where

$$M = \mathcal{M}\sigma \tag{32}$$

holds.

Illuminating the step to (28) resp. (32), we add the following basic annotation: As usual in mechanics resulting from unified field theories, fulfilling of the equivalence principle is a difficult challenge. We had to cope with this question up to 1995. In the paper [3] by investigations on canonical mechanics corresponding to our Projective Unified Field Theory we came to the finding that the scheme of canonical mechanics (apart from the usual dependence of the mass on velocity and metric) leads to the following dependence of the mass on the scalaric field:

$$M = M^{(N)} + \int \mathcal{M}(\sigma)d\sigma \qquad (M^{(N)} = \text{const})\,. \tag{33}$$

If the scalmass is independent of σ, it follows

$$M = M^{(N)} + \mathcal{M}\sigma\,. \tag{34}$$

Obviously, according to Newton's concept of mass, the constant mass $M^{(N)}$ in (33) has to be interpreted as the Newtonian mass of the body considered. If this quantity is unequal to zero, then our scalaric force term in the equation of motion (30)

$$F^k_{(S)} = -D\left(\sigma^{,k} + \frac{1}{c^2}\frac{\mathrm{d}\sigma}{\mathrm{d}\tau} u^k\right) \tag{35}$$

prevents fulfilling of the equivalence principle. Therefore starting with the papers [3] we studied the consequences of a tentative new concept of mass on the basis $M^{(N)} = 0$. This attempted idea is the basis of the formulas (28) to (32).Furthermore, in this way an important philosophical aspect of Mach's principle is fulfilled: The inertial mass M depends on the cosmological constellation ("far masses") expressed by the scalaric function σ.

4. Closed homogeneous isotropic cosmological model

4.1. COSMOLOGICAL SCENARIO AND BASIC COSMOLOGICAL EQUATIONS

The metric of such a world model reads

$$\mathrm{d}s^2 = K(\xi)\left[\mathrm{d}\vartheta^2 + \sin^2\vartheta\left(\mathrm{d}\theta^2 + \sin^2\theta\mathrm{d}\varphi^2\right)\right] - \mathrm{d}\xi^2\,, \tag{36}$$

where $K(\xi)$ with $\xi = x^4 = ct$ is the time-dependent world radius, and $\vartheta, \theta, \varphi$ are the polar angles.By arguments arising from the equation of motion (explained later) we were led to the following cosmological scenario [7] :

1. **Repulsion era (antigravitational era):** This era characterized by the repulsion between the existing particles starts at the time $t = 0$ by a (soft) big start (Urstart) with the value $\sigma(t = 0) = 0$ of the scalaric world function σ and ends at the time $t = t_0$ with the value $\sigma(t = t_0) = 1$. According to the present ideas in this period a gas mixture of quantum particles (quarks, leptons, gluons, protons, neutrons etc.) of an extremely high temperature existed.
2. **Attraction era (gravitative era):** This era characterized by the gravitative attraction between the particles and bodies begins at the time t_0 with the value $\sigma = 1$ of the scalaric world function σ and lasts till now. The gravitative force consists of the dominating attractive gravitational (metric) force and the repulsive scalaric force. In this era the nucleosynthesis and the forming of galaxies and stars happens.

Now the assumptions $\rho_0 = 0$ and $B_{kl}H^{kl} = 0$ (incoherent electromagnetic background radiation) are chosen. As it is well known, for the electromagnetic field the following relations hold:

$$\text{a)}\quad p_{(r)} = \frac{1}{3}w_{(r)}\,, \qquad \text{b)}\ \mu_{(r)} = \frac{1}{c^2}w_{(r)} \tag{37}$$

($p_{(r)}$ radiation pressure, $w_{(r)}$ radiation energy density, $\mu_{(r)}$ radiation mass density).

Further it is convenient to introduce the following quantities for the closed universe:

$$\begin{aligned}
&\text{a)}\quad V_{\cos} = 2\pi^2 K^3 && \text{(volume of the cosmos)},\\
&\text{b)}\quad M_{\cos} = 2\pi^2 \mu K^3 && \text{(mass of the cosmos)},\\
&\text{c)}\quad \mathcal{M}_{\cos} = 2\pi^2 \mu^{(\sigma)} K^3 && \text{(scalmass of the cosmos)},\\
&\text{d)}\quad D_{\cos} = 2\pi^2 \vartheta K^3 && \text{(scalerg of the cosmos)}\,.
\end{aligned} \tag{38}$$

Under the above assumptions from the general field equations (17) and (21) follow — partially after integration — the specialized equations (prime means derivative with respect to ξ)

$$\begin{aligned}
&\text{a)}\quad \frac{K''}{K} - \frac{2}{3}\sigma'^2 + \frac{\varkappa_0 \Lambda_0}{K^4} + \frac{\varkappa_0 \sigma}{6}\left(\vartheta + \frac{3p}{\sigma}\right) = 0\,,\\
&\text{b)}\quad \frac{1}{K^2}\left(K'^2 + 1\right) + \frac{1}{3}\sigma'^2 - \frac{\varkappa_0 \Lambda_0}{K^4} - \frac{\varkappa_0 \sigma}{3}\vartheta = 0\,,\\
&\text{c)}\quad \sigma'' + \frac{3}{K}K'\sigma' - \frac{\varkappa_0 \vartheta}{2} = 0\,,\\
&\text{d)}\quad \Lambda_0 = \frac{1}{3} w_{(r)} K^4
\end{aligned} \tag{39}$$

(Λ_0 electromagnetic radiation constant of the cosmos). Further from the continuum-mechanical equations (26) and (29) we obtain

$$\vartheta' + \frac{3}{K}\left(\vartheta + \frac{p}{\sigma}\right) K' = 0\,. \tag{40}$$

The equation (39a) can be derived by differentiation of (39b) and subsequent eliminations, i.e. the system to treat consists of the equations (39a), (39c) and (40).

In our first papers on cosmology on the basis of the field equations (1995) we followed the usual arguments to consider the cosmological matter as a dust-like incoherent quasi-perfect gas (stars, galaxies, intergalactic matter etc. as particles) with pressure $p = 0$. Later we generalized this simple model, already leading to a cosmology without big bang, to the following more realistic cosmological model with pressure:

The closed homogeneous isotropic cosmos mainly consists of a proper cosmological gas of dark matter particles (dm-particles) which strongly dominates the visual (normal) matter of stars, galaxies etc. (percentage perhaps less than 1%) which "swim" in this "cosmological sea of the dm-particle gas" ("dm-gas"). For simplicity we restricted our analytical calculations to a one-sort gas obeying the Boltzmann-Maxwell statistics. Based on a relativistic treatment of the dm-particles whose velocity may be related to the cosmological expansion process we were led to the equation of state for a perfect gas

$$p = n\mathrm{k}T \tag{41}$$

(n particle number density, T kinetic temperature of the gas, k Boltzmann constant), but with the following specific relationship of the kinetic temperature to the cosmological fields K and σ:

$$T = \frac{m_0^{(\sigma)} c^2 B_0 \sqrt{-g_{44}}}{3\mathrm{k}K\sqrt{1+\frac{\sigma^2 K^2}{B_0^2}}}, \tag{42}$$

where $m_0^{(\sigma)}$ is the scalmass of the dm-particles, B_0 is a constant of integration determined later.

For practical reasons it is convenient to perform the following cosmological rescaling

$$\text{a)}\quad K = A_0 L\,, \quad \xi = A_0 \eta \quad \text{with} \quad \text{b)}\quad \eta = \frac{ct}{A_0} \tag{43}$$

(L rescaled world radius, η rescaled time-like coordinate, $A_0 = 10^{27}$ cm is a rescaling factor). Now factorizing $B_0 = A_0/\sqrt{C_0}$ is comfortable. Then the equation of state takes the shape

$$p = \frac{\vartheta\sigma\sqrt{-g_{44}}}{3(1+C_0 L^2\sigma^2)}\,. \tag{44}$$

This expression has to be inserted into the system of differential equations (39a,c) and (40). After rescaling results

$$\begin{aligned}
&\text{a)}\quad \ddot{L} - \frac{2}{3}L\dot{\sigma}^2 + \frac{\Delta}{L^3} + \widehat{\varkappa}\sigma L\vartheta\left(1+\frac{1}{1+C_0L^2\sigma^2}\right) = 0\,,\\
&\text{b)}\quad \ddot{\sigma} + \frac{3}{L}\dot{L}\dot{\sigma} - 3\widehat{\varkappa}\vartheta = 0\,,\\
&\text{c)}\quad \dot{\vartheta} + \frac{1}{L}\vartheta\dot{L}\left(3+\frac{1}{1+C_0L^2\sigma^2}\right) = 0
\end{aligned} \tag{45}$$

(dot means derivative with respect to η), where the abbreviations

$$\text{a)}\quad \Delta = \frac{\varkappa_0\Lambda_0}{A_0^2}\,, \quad \text{b)}\quad \widehat{\varkappa} = \frac{\varkappa_0 A_0^2}{6} = 3.4617\times 10^5\ \mathrm{g^{-1}cm\ s^2} \tag{46}$$

are used.

4.2. NUMERICAL TREATMENT OF THE SYSTEM OF DIFFERENTIAL EQUATIONS

The subsequent problem consists in the choice of a minimum of free parameters with the aim to describe a maximum of empirical facts. For this purpose we remember the present empirical value (index p means present time)

$$T_{ph,p} = 2.728\ \mathrm{K} \tag{47}$$

of the temperature of the electromagnetic background radiation (photon temperature). Finally we arrived via (39d) at the choice

$$\Delta = 2.22415 \times 10^{-7} \tag{48}$$

for one of the free parameter in the differential equation (45a).

Further the initial conditions had to be chosen such that a reasonable outcome, compared with the empirical astrophysical facts, could be reached. We were satisfied with the results by choosing the value $C_0 = 5{\cdot}10^{-4}$ and following initial conditions:

$$\begin{aligned} &\text{a)} \quad L(\eta = 0) = 10^{-4}\,,\ \dot{L}(\eta = 0) = 4.6088486771411\,, \\ &\text{b)} \quad \sigma(\eta = 0) = 0\,,\ \dot{\sigma}(\eta = 0) = 0\,, \\ &\text{c)} \quad \vartheta(\eta = 0) = 2.1 \times 10^{8}\ \mathrm{g\ cm^{-1}s^{-2}}\,, \end{aligned} \tag{49}$$

where the second (numerical) initial condition resulted by exploiting of (39b). The subsequent numerical calculations were performed with the help of Maple and Mathematica for control (partly with an accuracy of digits = 27).

Our main result is a cosmological model without big bang. We called the basic temporal begin of the cosmos received "big start" (Urstart).

Figure 1. Temporal course of the rescaled world radius immediately after the big start

Figure 2. Temporal course of the rescaled world radius for the whole time of existence of the cosmos

Fig. 1 shows the temporal course of the rescaled world radius L (ordinate) as a function of the rescaled time η (abscissa) immediately after the big start. The unit $\Delta\eta = 1$ approximately corresponds to 1 billion y (y= year), i.e. the range on the abscissa means about 1000 y. Fig. 2 shows the temporal course of the rescaled world radius for the whole time scale between the big start and about 19 billion y (with a period of about 2.5 billion y, possibly being interesting with respect to the heat balance of the planets, too). Fig. 3 exhibits the temporal course of the scalaric world function σ between the big start and about 19 billion y.

Figure 3. Temporal course of the scalaric world function for the whole time of existence of the cosmos

Figure 4. Temporal course of the relative frequency shift backwards from the present time (unit $\Delta\eta = 1$ corresponds to the distance of circa 1 billion light years)

The results for some cosmological quantities at the big start are:

$$\text{a)}\quad T_{ph}(\eta = 0) = 2.55 \cdot 10^4 \text{ K}\,, \quad \text{b)}\, T(\eta = 0) = 9.72 \cdot 10^{41} \cdot m_0^{(\sigma)} \text{ g}^{-1} \text{ K}\,. \tag{50}$$

The duration of the repulsion era is given by $\eta_{RP} = 1.0257 \cdot 10^{-7}$, i.e $t_{RP} =$ 108.5 y.

For the astrophysical evaluation of this cosmological theory it is necessary to present some main numerical values for the present time:

$$\begin{array}{ll}
\text{a)}\quad \eta_p = 18\,, \quad \text{b)}\, t_p = 19 \times 10^9 \text{ y} & \text{(age of the cosmos),} \\
\text{c)}\quad K_p = 9.357.. \times 10^{26} \text{ cm} & \text{(radius of the cosmos),} \\
\text{d)}\quad L_p = 0.9357...\,, & \text{e)}\quad \dot{L}_p = 0.0684...\,, \\
\text{f)}\quad \sigma_{cp} = 59.7731\,, & \text{g)}\quad \dot{\sigma}_{cp} = 1.0018, \\
\text{h)}\quad \mu_p = 2.4 \times 10^{-27} \text{ g cm}^{-3}, & \text{i)}\quad H_p = 67.8 \text{ km/(sMpc)}\,.
\end{array} \tag{51}$$

In Fig. 4 we present the relative frequency shift (redshift) $z(\eta)$ as a function of the distance (backwards from the present time). Astrophysically interesting in this figure is the waviness (non-monotony) of the curve (equal redshift values for different distances !).

5. Solution for a point-like body

5.1. EXACT SOLUTION

Here we refer to our publication [8]. Using the well–known metric

$$\mathrm{d}s^2 = e^{\alpha(r)}\mathrm{d}r^2 + r^2\left(\sin^2\theta \mathrm{d}\varphi^2 + \mathrm{d}\theta^2\right) - e^{\beta(r)}(\mathrm{d}x^4)^2 \tag{52}$$

we obtain from the gravitational field equation (17)

$$\begin{aligned} &\text{a)}\quad \beta' - \alpha' + \frac{2}{r}(1 - e^{\alpha}) = 0\,, \quad \text{b)}\quad \alpha' + \beta' + 2r\sigma'^2 = 0\,, \\ &\text{c)}\quad \beta'' + \frac{1}{2}\beta'(\beta' - \alpha') + \frac{1}{r}(3\beta' - \alpha') + \frac{2}{r^2}(1 - e^{\alpha}) = 0 \end{aligned} \tag{53}$$

and from the scalaric field equation (21)

$$\left(r^2\sigma' e^{\frac{1}{2}(\beta-\alpha)}\right)' = 0 \tag{54}$$

(prime means derivative with respect to r). Rather lengthy calculations lead to the exact solution

$$r = \widehat{r}\frac{\sqrt{1 - \tau_1 - \Lambda^2}}{1 - \Lambda}\left(\frac{\sqrt{1 - \tau_1} - \Lambda}{\sqrt{1 - \tau_1} + \Lambda}\right)^{\frac{1}{2\sqrt{1-\tau_1}}} \tag{55}$$

with

$$\Lambda = \sqrt{1 + \tau_1(e^{\alpha} - 1)} \tag{56}$$

and

$$e^{\beta} = \left(\frac{\tau_1\alpha_1}{2r}\right)^2 \frac{1 + \frac{1}{\tau_1}(\Lambda^2 - 1)}{(\Lambda - 1)^2}\,, \tag{57}$$

$$\sigma = \bar{\sigma} - \frac{1}{2}\sqrt{\tau_1}\beta \tag{58}$$

($\widehat{r}$, τ_1, α_1 and $\bar{\sigma}$ are constants of integration). Let us mention that first investigations apparently lead to the conclusion that our above exact solution for a point-like mass does not exhibit a horizon (as in the Einstein theory), i.e. black holes in the usual sense do not exist in PUFT.

The Schwarzschild solution is the special case $\tau_1 = 0$, $\sigma = \bar{\sigma}$. For physical applications we need explicite solutions up to the second order in $1/r$. By Taylor expansion, in the first steps needed up to the third order, we arrive at ($\alpha_1 = \widehat{r} = r_g$ gravitational radius)

$$\begin{aligned} &\text{a)}\quad e^{\alpha} = 1 + \frac{r_g}{r} + \frac{r_g^2\left(1 + \frac{\tau_1}{4}\right)}{r^2}\,, \\ &\text{b)}\quad e^{\beta} = 1 - \frac{r_g}{r}\quad,\quad \beta = -\frac{r_g}{r}\left(1 + \frac{r_g}{2r}\right)\,, \\ &\text{c)}\quad \sigma = \bar{\sigma} + \frac{1}{2r}r_g\sqrt{\tau_1}\left(1 + \frac{r_g}{2r}\right)\,. \end{aligned} \tag{59}$$

We are left with the 3 parameters r_g, τ_1 and $\bar{\sigma}$ which now have to be determined further. For this reason we present the non-relativistic results for the fields of a static sphere (r_0 = radius of the sphere) .

5.2. APPROXIMATE SOLUTION

In the following we list the fields up to the first order in the gravitational constant.

5.2.1. *External fields:*

$$\text{a)}\quad \phi_e = -\frac{\gamma_N \mathcal{M}_c \sigma_c}{r} + \phi_{e0}\,, \qquad \text{b)}\ \sigma_e = \frac{\gamma_N \mathcal{M}_c}{rc^2} + \sigma_c \tag{60}$$

(ϕ_{e0}, σ_c constants of integration), where ϕ is the Newtonian gravitational potential related to g_{44} by

$$g_{44} = -\left(1 + \frac{2\phi}{c^2}\right)\,. \tag{61}$$

Furthermore, γ_N is the Newtonian gravitational constant related to the Einsteinian gravitational constant $\varkappa_0$ by

$$\varkappa_0 = \frac{8\pi\gamma_N}{c^4}\,. \tag{62}$$

$\mathcal{M}_c$ is the scalmass of the central body, and $\sigma_c = \sigma_c(t)$ is (treated as a constant of integration) the scalaric world function with its slight temporal (adiabatic) variation, compared to the temporal variations by the motion of the bodies considered later.

5.2.2. *Internal fields:*

$$\begin{aligned} \text{a)}\quad \phi_i &= \tfrac{\gamma_N \mathcal{M}_c \sigma_c}{2r_0}\left(\tfrac{r^2}{r_0^2} - 3\right) + \phi_{e0}\,, \\ \text{b)}\quad \sigma_i &= -\tfrac{\gamma_N \mathcal{M}_c}{2c^2 r_0}\left(\tfrac{r^2}{r_0^2} - 3\right) + \sigma_c\,. \end{aligned} \tag{63}$$

Let us mention that we fulfilled the continuity conditions for ϕ and σ as well as for the first derivatives of these functions.

6. Mechanical motion of a test body

6.1. RELATIVISTIC MOTION AND EINSTEIN EFFECTS

As mentioned above, our concept of mass and scalmass has been founded such that the equivalence principle is fulfilled completely. Starting point for treating the relativistic motion of a test body is the equation of motion (30) for the case of vanishing electric charge of the body: $Q = 0$. We obtain the specialized equation of motion

$$u^k{}_{;l} u^l = -c^2\left((\ln\sigma)^{,k} + \frac{1}{c^2}\frac{\mathrm{d}\ln\sigma}{\mathrm{d}\tau}u^k\right)\,. \tag{64}$$

Comparing the results (59) and (60) we obtain the following identification of the parameters

$$\text{a)}\quad r_g = \frac{2\gamma_N \mathcal{M}_c \sigma_c}{c^2}\,, \quad \text{b)}\quad \sqrt{\tau_1} = \frac{1}{\sigma_c}\,, \quad \text{c)}\quad \sigma_c = \bar{\sigma}\,. \tag{65}$$

Applying equation (64) to the Einstein effects and comparing the results with the Newtonian mechanics leads to the relationship between the gravitational radius r_g in our theory (65a) and the gravitational radius $r_g^{(N)}$ in the Einstein theory referring to the Newton theory:

$$r_g^{(N)} = r_g \left(1 - \frac{1}{\sigma_c^2}\right) \tag{66}$$

where the definition

$$r_g^{(N)} = \frac{2\gamma_N M_c^{(N)}}{c^2} \tag{67}$$

holds ($\sigma_c = \sigma_p$ present value of the scalaric world function, $M_c^{(N)}$ Newtonian gravitational mass of the center).

In the following we list our results for the Einstein effects.

6.1.1. *Advance of the periastron:*

$$\frac{\Delta\varphi}{(\Delta\varphi)_{\text{Einstein}}} = \frac{1 - \frac{2}{3\sigma_c^2} - \frac{1}{6\sigma_c^4}}{\left(1 - \frac{1}{\sigma_c^2}\right)^2}\,. \tag{68}$$

Using for the scalaric world function the present value (51) $\sigma_c = 59.7731$, we obtain the universal correction

$$\left(\frac{\Delta\varphi}{(\Delta\varphi)_{\text{Einstein}}}\right)_p = 1.0004 \tag{69}$$

induced by the cosmological expansion.

6.1.2. *Deflection of electromagnetic waves:*

$$\text{a)}\quad \frac{\Delta\chi}{(\Delta\chi)_{\text{Einstein}}} = \frac{1}{1 - \frac{1}{\sigma_c^2}}\,, \quad \text{b)}\quad \left(\frac{\Delta\chi}{(\Delta\chi)_{\text{Einstein}}}\right)_p = 1.0003\,.$$

6.1.3. *Frequency shift of electromagnetic waves:*

$$\text{a)}\quad \frac{\Delta\omega}{(\Delta\omega)_{\text{Einstein}}} = \frac{1}{1 - \frac{1}{\sigma_c^2}}\,, \quad \text{b)}\quad \left(\frac{\Delta\omega}{(\Delta\omega)_{\text{Einstein}}}\right)_p = 1.0003\,.$$

Referring to the empirically oriented literature, we find that the results of the measuring values do not contradict the above theoretical values.

6.2. NON-RELATIVISTIC MOTION

Applying the approximate result (59) to the equation of motion (30) leads to the following non–relativistic equation of motion of a test body:

$$M\left(\frac{\mathrm{d}\boldsymbol{v}}{\mathrm{d}t}+\operatorname{grad}\Psi+\boldsymbol{v}\frac{\mathrm{d}\ln\sigma}{\mathrm{d}t}\right)=Q\left(\boldsymbol{E}+\frac{1}{c}\boldsymbol{v}\times\boldsymbol{B}\right) \tag{70}$$

with the following meaning of the symbols used (M inertial mass and $\boldsymbol{v}$ velocity of the moving body, respectively):

$$\Psi=-\frac{\gamma_N M_c^{(S)}}{r} \tag{71}$$

with ($\mathcal{M}_c$ scalmass of the central body)

$$M_c^{(S)}=\mathcal{M}_c\sigma^{(S)} \tag{72}$$

and

$$\sigma^{(S)}=\frac{\sigma^2-1}{\sigma}\ \text{(scalaric correction factor)}\,. \tag{73}$$

As shown in detail in [8], from (70) it becomes obvious that the acting "gravitative force" on a moving test body

$$\boldsymbol{F}_{\text{gravitative}}=\boldsymbol{F}_{\text{gravitational}}+\boldsymbol{F}_{\text{scalaric}}=-M\ \operatorname{grad}\Psi=-\frac{\gamma_N M M_c^{(S)}}{r^3}\boldsymbol{r} \tag{74}$$

consists of two parts, namely the attracting gravitational force

$$\boldsymbol{F}_{\text{gravitational}}=-M\ \operatorname{grad}\phi=-\frac{\gamma_N M M_c}{r^3}\boldsymbol{r} \tag{75}$$

and the repulsing scalaric force

$$\boldsymbol{F}_{\text{scalaric}}=-M\ \operatorname{grad}\Sigma=\frac{\gamma_N M\mathcal{M}_c}{\sigma r^3}\boldsymbol{r}\,, \tag{76}$$

where

$$\Psi=\phi+\Sigma \tag{77}$$

with

$$\text{a)}\quad \phi=-\frac{\gamma_N M_c}{r}\,,\qquad \text{b)}\ \Sigma=\frac{\gamma_N\mathcal{M}_c}{\sigma r} \tag{78}$$

holds. This finding was the reason for our dividing the evolution of the cosmos into the repulsion era ($0\le\sigma<1$) and the attraction era ($\sigma\ge 1$).

These considerations open the possibility of defining the "effective gravitational factor" being time-dependent (we don't use the term "gravitational constant") by

$$G = \gamma_N \sigma^{(S)}, \tag{79}$$

since we believe that this definition is appropriate for the experiments (based on the equation of motion of a test body but not on the definition of the gravitative potential energy, as we did earlier). In this context one should realize that this definition of G, being different from the usual one, is based on our scalmass concept of time-independent masses. Detailed calculations lead to the following expression for the relative time dependence (as a universal cosmological effect) of the effective empirical gravitational factor:

$$\frac{1}{G}\frac{\mathrm{d}G}{\mathrm{d}t} = \frac{1+1/\sigma^2}{1-1/\sigma^2}\frac{\mathrm{d}\ln\sigma}{\mathrm{d}t}. \tag{80}$$

Our numerical choice of the parameters obtained above leads to the value

$$\left(\frac{1}{G}\frac{\mathrm{d}G}{\mathrm{d}t}\right)_p = 1.58 \times 10^{-11}\ \mathrm{y}^{-1}. \tag{81}$$

As it is well known, since a rather long time intensive international affords were undertaken in order to measure this quantity (see the corresponding papers of G. T. Gillies, V. Melnikov, A. J. Sanders etc. in this volume).

Let us finally mention that on the basis of this mass concept the gravitative potential energy between two bodies with the (inertial) masses $\mathcal{M}_1$ and $\mathcal{M}_2$ (r distance between both bodies) reads

$$V = -\frac{\gamma_N \mathcal{M}_1 \mathcal{M}_2 (\sigma^2 - 1)}{r}. \tag{82}$$

7. Adiabatic scalaric approximation of the equation of motion

As shown recently [8], the equation of motion (70) of an electrically uncharged test body orbiting around a central body because of the conservation of the angular momentum of the body (R radial coordinate)

$$\text{a)}\quad L_0 = \mathcal{M} F_0 \quad \text{with} \quad \text{b)}\quad F_0 = \sigma R v_\phi \tag{83}$$

takes the form (in this section and later the dot means derivative with respect to the time t)

$$\ddot{R} - \frac{F_0^2}{\sigma^2 R^3} + \frac{\bar{K}}{R^2} + \frac{1}{\sigma}\dot{R}\dot{\sigma} = 0, \tag{84}$$

where

$$\text{a)}\quad \bar{K} = \gamma_N \mathcal{M}_c \sigma^{(S)}, \quad \text{b)}\quad v_\phi = R\dot{\phi} \tag{85}$$

holds ($\mathcal{M}_c$ scalaric mass of the central body, v_ϕ azimuthal velocity of the moving body). The transition $R(t)$ to $R(\phi)$ performed as usual and the transformation $R = 1/u$ lead to

$$\frac{\mathrm{d}^2 u}{\mathrm{d}\phi^2} + u = \frac{\bar{K}\sigma^2}{F_0^2}\,. \tag{86}$$

In Newtonian mechanics the inhomogeneity on the right hand side of this equation is a constant, i.e. we have to solve a linear inhomogeneous differential equation. In our theory the inhomogeneity contains a slight cosmological time dependence, i.e. we are confronted with a rather complicated mathematical problem. But since the motion of the body considered may be rather fast compared to the cosmological temporal variation, we can restrict our further investigation to this case. We call the procedure applied "adiabatic scalaric approximation". Then the result of integrating (86) is

$$u = A_S \cos(\phi - \phi_0) + \frac{\gamma_N \mathcal{M}_c \sigma(\sigma^2 - 1)}{F_0^2} \tag{87}$$

(A_S scalaric orbital coefficient as a constant of integration, ϕ_0 constant of integration). Using the scalaric orbital radius R_S and the scalaric excentricity ϵ_S both defined by

$$\text{a)}\quad R_S = \frac{F_0^2}{\gamma_N \mathcal{M}_c \sigma(\sigma^2 - 1)}\,, \quad \text{b)}\quad \epsilon_S = A_S R_S\,, \tag{88}$$

respectively, then equation (87) takes the form

$$R = \frac{R_S}{1 + \epsilon_S \cos(\phi - \phi_0)}\,. \tag{89}$$

By differentiation of (88a) we find the result

$$\dot{R}_S = -\frac{F_0^2(3\sigma^2 - 1)}{\gamma_N \mathcal{M}_c \sigma^2(\sigma^2 - 1)^2}\,\dot{\sigma}. \tag{90}$$

Let us now define and list some quantities further used:

$$\begin{aligned}
&\text{a)}\quad \omega_S = \dot{\phi} = \frac{\gamma_N^2 \mathcal{M}_c^2 \sigma(\sigma^2 - 1)^2}{F_0^3},\\
&\text{b)}\quad \dot{\omega}_S = \ddot{\phi} = \frac{(\gamma_N \mathcal{M}_c)^2(\sigma^2 - 1)(5\sigma^2 - 1)}{F_0^3}\dot{\sigma}\,,\\
&\text{c)}\quad v_{\phi S} = \frac{F_0}{\sigma R_S} = \frac{\gamma_N \mathcal{M}_c(\sigma^2 - 1)}{F_0}\,, \quad \text{d)}\quad a_S = \dot{v}_{\phi S} = \frac{2\gamma_N \mathcal{M}_c \sigma}{F_0}\dot{\sigma},\\
&\text{e)}\quad \tau_S = \frac{2\pi}{\omega_S} = \frac{2\pi F_0^3}{\gamma_N^2 \mathcal{M}_c^2 \sigma(\sigma^2 - 1)^2}\,, \quad \text{f)}\ \dot{\tau}_S = -\frac{2\pi}{\omega_S^2}\dot{\omega}_S\,, \quad \text{g)}\ \dot{\epsilon}_S = A_S \dot{R}_S\,.
\end{aligned} \tag{91}$$

Physically remarkable are the signs of these cosmological universal effects: positive value of the angular acceleration (secular acceleration); negative values of the time derivatives of the scalaric orbital radius (decrease), revolution period (decrease), excentricity (transition from elliptic to cyclic orbits).

Using some values of (51) we find following numerical results:

$$\begin{aligned} &\text{a)} \quad \left(\frac{\dot{R}_S}{R_S}\right)_p = \left(\frac{\dot{\epsilon}_S}{\epsilon_S}\right)_p = -4.74 \times 10^{-11}\mathrm{y}^{-1}\,, \\ &\text{b)} \quad \left(\frac{\dot{\tau}_S}{\tau_S}\right)_p = -\left(\frac{\dot{\omega}_S}{\omega_S}\right)_p = -7.9 \times 10^{-11}\ \mathrm{y}^{-1}\,, \\ &\text{c)} \quad \left(\frac{\dot{v}_{\phi S}}{v_{\phi S}}\right)_p = 3.16 \times 10^{-11}\ \mathrm{y}^{-1}\,. \end{aligned} \tag{92}$$

Finally in this section we give numeric examples for the orbital motion of some objects (departures of our theory from Newtonian mechanics):

Sun around the center of the galaxy:

$$\text{a)}\ (\dot{R}_S)_p = -3.94 \times 10^4\ \mathrm{cm\,s^{-1}}\,, \qquad \text{b)}\ (\ddot{\phi})_p = 4.31'' \times 10^{-9}/(100\ \mathrm{y})^2\,. \tag{93}$$

Earth around the sun:

$$\text{a)}\ (\dot{R}_S)_p = -2.24 \times 10^{-5}\ \mathrm{cm\,s^{-1}}\,, \qquad \text{b)}\ (\ddot{\phi})_p = 1.03''/(100\ \mathrm{y})^2\,. \tag{94}$$

Moon around the earth:

$$\text{a)}\ (\dot{R}_S)_p = -5.77 \times 10^{-8}\ \mathrm{cm\,s^{-1}}\,, \qquad \text{b)}\ (\ddot{\phi})_p = 13.52''/(100\ \mathrm{y})^2\,. \tag{95}$$

Satellite around the earth (height over the earth = 200 km):

$$\text{a)}\ (\dot{R}_S)_p = -9.86 \times 10^{-10}\ \mathrm{cm\,s^{-1}}\,, \qquad \text{b)}\ (\ddot{\phi})_p = 6.13'' \times 10^3/(100\ \mathrm{y})^2\,. \tag{96}$$

In order to avoid misunderstandings, we would like to emphasize that these effects treated are (pure) universal cosmological effects. Of course, the orbiting bodies are subjected to a lot of additional influences as friction etc. As an example we mention the tidal effects acting on the moon with the empirical result of its drifting apart from the earth with the radial velocity of $v_R \approx 3.8$ cm/s.

8. Heat production in a moving body

8.1. TEST BODY, RIGID BODY AND BINARY SYSTEM

Considering the equation of motion (70) one immediately recognizes the force term

$$\boldsymbol{F}_B = -\mathcal{M}\frac{\mathrm{d}\sigma}{\mathrm{d}t}\boldsymbol{v} \tag{97}$$

being linear in the velocity and acting as a friction force term for the expansion era of the cosmos. We understand that this cosmological deceleration force (short: bremsforce) leads to the cosmologically induced internal production of deceleration heat (short: bremsheat):

$$P_B \equiv -\frac{\mathrm{d}Q_B}{\mathrm{d}t} = -\boldsymbol{F}_B \boldsymbol{v} = \mathcal{M}\boldsymbol{v}^2 \frac{\mathrm{d}\sigma}{\mathrm{d}t} \ . \tag{98}$$

The corresponding expressions for a continuum read

$$\text{a)} \quad \boldsymbol{F}_B = -\mu^{(\sigma)} \frac{\mathrm{d}\sigma}{\mathrm{d}t} \boldsymbol{v} \ , \quad \text{b)} \quad \frac{\mathrm{d}q_B}{\mathrm{d}t} = -\mu^{(\sigma)} \boldsymbol{v}^2 \frac{\mathrm{d}\sigma}{\mathrm{d}t} \ . \tag{99}$$

In order to apply this result to a rigid body with translational and rotational motion we have generalized the well-known Newtonian mechanics of a rigid body to our mechanics (the difference lies in the time dependence of the factor σ). The main results are:

Kinetic energy:

$$T = T^{\text{transl}} + T^{\text{rot}} \tag{100}$$

with

$$\text{a)} \quad T^{\text{transl}} = \frac{1}{2} M \dot{\boldsymbol{r}}_c^2 \ , \quad \text{b)} \quad T^{\text{rot}} = \frac{1}{2} \sum_{a,b=1}^{3} I_{ab} \omega_a \omega_b \ , \tag{101}$$

where

$$I_{11} = \sum_{\Omega} M_\Omega (\eta_\Omega^2 + \zeta_\Omega^2) \ , \quad I_{12} = -\sum_{\Omega} M_\Omega \xi_\Omega \eta_\Omega \ , \tag{102}$$

is the inertial tensor ($M = \mathcal{M}\sigma$ mass of the rigid body, $\boldsymbol{r}_c$ radius vector to the center of mass, ω_a components of the angular velocity vector).

Angular momentum:

$$\boldsymbol{L} = \boldsymbol{L}^{\text{transl}} + \boldsymbol{L}^{\text{rot}} \tag{103}$$

with

$$\text{a)} \quad \boldsymbol{L}^{\text{transl}} = M \boldsymbol{r}_c \times \dot{\boldsymbol{r}}_c \ , \quad \text{b)} \quad \boldsymbol{L}^{\text{rot}} = \sum_{\Omega} M_\Omega \bar{\boldsymbol{r}}_\Omega \times (\boldsymbol{\omega} \times \bar{\boldsymbol{r}}_\Omega) \ , \tag{104}$$

where

$$L_a^{\text{rot}} = \sum_{b=1}^{3} I_{ab} \omega_b \ . \tag{105}$$

Force moment:

$$\boldsymbol{M} = \boldsymbol{M}^{\text{transl}} + \boldsymbol{M}^{\text{rot}} \tag{106}$$

with

$$\text{a)} \quad \boldsymbol{M}^{\text{transl}} = \boldsymbol{r}_c \times \boldsymbol{F} \ , \quad \text{b)} \quad \boldsymbol{M}^{\text{rot}} = \sum_{\Omega} \bar{\boldsymbol{r}}_\Omega \times \boldsymbol{F}_\Omega \ , \tag{107}$$

where

$$\boldsymbol{F} = \sum_{\Omega} \boldsymbol{F}_{\Omega} = \boldsymbol{F}^{\text{ext}} + \boldsymbol{F}^{\text{int}} \tag{108}$$

($\mathbf{F}_{\Omega}$ force on the particle Ω, $\bar{\boldsymbol{r}}_{\Omega}$ radius vector to the particle Ω from the center of mass).

The equation of motion of a rigid body

$$\frac{\mathrm{d}\boldsymbol{L}}{\mathrm{d}t} = \boldsymbol{M} \tag{109}$$

splits into the two equations

$$\text{a)} \quad \frac{\mathrm{d}\boldsymbol{L}^{\text{transl}}}{\mathrm{d}t} = \boldsymbol{M}^{\text{transl}}, \quad \text{b)} \frac{\mathrm{d}\boldsymbol{L}^{\text{rot}}}{\mathrm{d}t} = \boldsymbol{M}^{\text{rot}}. \tag{110}$$

The first equation is identical with the translational equation of motion

$$\text{a)} \quad \frac{\mathrm{d}(M\dot{\boldsymbol{r}}_c)}{\mathrm{d}t} = \boldsymbol{F} \quad \text{with} \quad \text{b)}\, \boldsymbol{p}_c = M\dot{\boldsymbol{r}}_c \quad \text{(momentum)}. \tag{111}$$

If no force is acting, then follows

$$\dot{\boldsymbol{r}}_c = \frac{\boldsymbol{v}_0}{\sigma} \text{ (constant of integration)}.$$

From this result we learn that the velocity of a force-free body decreases by the expansion of the cosmos (effect of homogenization).

If we refer to a rigid body with compensating internal forces, then in the case of gravitative forces the force reads

$$\text{a)} \quad \boldsymbol{F} = \boldsymbol{F}^{\text{ext}} \quad \text{with} \quad \text{b)}\, \boldsymbol{F}^{\text{ext}} \approx -\frac{\gamma_N M M_c^{(S)}}{r_c^3}\boldsymbol{r}_c \tag{112}$$

(M mass of the rigid body, $M_c^{(S)}$ gravitative mass of the external body, $r_c = |\boldsymbol{r}_c|$).

Evaluating the above result (98) and applying the findings here obtained, we get for the bremsheat production of a rigid body with translational and rotational motion

$$P_B = \left(\frac{\gamma_N M M_c^{(S)}}{R_S} + \sum_{a,b=1}^{3} I_{ab}\omega_a\omega_b \right) \frac{\mathrm{d}\ln\sigma}{\mathrm{d}t} \tag{113}$$

and hence for a sphere (r_0 radius of the sphere)

$$P_B = M \left(\frac{\gamma_N M_c^{(S)}}{R_S} + \frac{2}{5} r_0^2 \omega^2 \right) \frac{\mathrm{d}\ln\sigma}{\mathrm{d}t} \tag{114}$$

with

$$I = \frac{2}{5} M r_0^2 \tag{115}$$

It is convenient to define the ratio of the orbital to the rotational effect:

$$S_B = \frac{5\gamma_N M_c^{(S)}}{2R_S r_0^2 \omega^2} \,. \tag{116}$$

For a binary system the bremsheat production is given by ($\boldsymbol{r} = \boldsymbol{r}_1 - \boldsymbol{r}_2$ relative radius vector)

$$\text{a)} \quad P_B = M^{\text{red}} \dot{\boldsymbol{r}}^2 \frac{d \ln \sigma}{dt} \quad \text{with} \quad \text{b)} \quad M^{\text{red}} = \frac{M_1 M_2}{M_1 + M_2} \text{ (reduced mass)} \,. \tag{117}$$

8.2. NUMERICAL EVALUATION

Here we evaluate the formulas (114) and (116) for the present time. Remembering numerical results of (51) and referring to Newton's mass interpretation in this context

$$\text{a)} \quad M^{(N)} = \mathcal{M} \sigma_p \,, \quad \text{b)} \; M_c^{(N)} = \mathcal{M}_c \sigma_p^{(S)}, \tag{118}$$

we obtain

$$\begin{aligned} \text{a)} \quad P_B &= 5.03 \cdot 10^{-19} \, M^{(N)} \left(\frac{\gamma_N M_c^{(N)}}{R_S} + 0.4 \, r_0^2 \omega^2 \right) \text{s}^{-1} \,, \\ \text{b)} \quad S_B &= 1.67 \cdot 10^{-7} \frac{M_c^{(N)}}{R_S r_0^2 \omega^2} \text{g}^{-1} \text{ cm}^3 \text{ s}^{-2}. \end{aligned} \tag{119}$$

There is not space enough here to list the used astronomical values for masses, distances, radii, angular velocities etc. For details one should consult special literature [9], [10] and [11]. Therefore, in order to give a numerical impression we only list some final results with respect to considerations on volcanicity and seismicity induced by the cosmological expansion.

Earth (as center):

Moon:

$P_B = 3.8 \times 10^{17} \text{erg s}^{-1}$, $S_B = 1.2 \times 10^5$ (orbital effect prevailing).

Empirical value: $P_{\text{emp}} \approx 10^{19} \text{erg s}^{-1}$.

Satellite (mass: 10^6 g, height over the earth: 200 km):

$P_B = 0.3 \text{ erg s}^{-1}$.

Jupiter (as center):

Moon Io:

$P_B = 1.4 \times 10^{20} \text{ erg s}^{-1}$.

Moon Kallisto:

$P_B = 3.6 \times 10^{19}$ erg s^{-1}.

Sun (as center):

Earth:

$P_B = 2.7 \times 10^{22}$ erg s^{-1}, $S_B = 10^4$ (orbital effect prevailing).
Empirical value: $P_{\text{emp}} = 2.5 \times 10^{20}$ erg s^{-1}.

Jupiter:

$P_B = 2.3 \times 10^{24}$ erg s^{-1}, $S_B = 2.4$ (orbital effect slightly prevailing).
Empirical value: $P_{\text{emp}} = 6.4 \times 10^{24}$erg s^{-1}.

Saturn:

$P_B = 3.8 \times 10^{23}$ erg s^{-1}, $S_B = 2.4$ (orbital effect slightly prevailing).
Empirical value: $P_{\text{emp}} = 4.6 \times 10^{23}$ erg s^{-1}.

Center of the galaxy:

Sun:

$P_B = 4.9 \times 10^{29}$ erg s^{-1}, $S_B = 3 \times 10^4$ (orbital effect prevailing).
Empirical value (solar constant): $P_{\text{emp}} = L_\odot = 3.847 \times 10^{33}$ erg s^{-1} (measured effect explained by nuclear fusion).

White dwarves (mean values):

$P_B = 2.7 \times 10^{29}$ erg s^{-1} (orbital effect).
Empirical value: $P_{\text{emp}} \approx 10^{-4} L_\odot = 3.847 \times 10^{29}$ erg s^{-1}.

Sagittarius *:

If we take the empirical values [11]: $M^{(N)} = 5.19 \times 10^{39}$ (mass), $L = 10^6 L_\odot$ (luminosity), we arrive at ($L \to P_B$)
$P_B = \frac{1}{R_S} \times 3.1 \times 10^{58}$ g cm^3 s^{-3} (orbital effect). Comparing both last formulas gives the radius of the orbit $R_S = 8.1 \times 10^{18}$ cm .

Sagittarius * (as center):

Object S1:

Tentatively using for the mass the value of the mass of the sun and further from the references quoted above for the radius of the orbit $R_S = 1.8 \times 10^{16}$ cm, we find $P_B = 1.9 \times 10^{31}$ erg s^{-1} $\approx 5 \times 10^{-3} L_\odot$ (orbital effect).

Rotating body:

Let us finally treat the separate rotational effect contained in (119a). If we take into account the stability at the equator of the rotating body ($M_c^{(N)} \to M^{(N)}$),

$$(r_0 \omega)^2 \approx \frac{\gamma_N M^{(N)}}{r_0}, \tag{120}$$

we arrive at

$$P_B = 1.34 \cdot 10^{-26} \frac{(M^{(N)})^2}{r_0} \text{ g}^{-1} \text{ cm}^3 \text{ s}^{-3}. \tag{121}$$

For illustration numerical values of the above quantities were recently calculated for specific data of pulsars and quasars. For the special pulsar values $M^{(N)} =$

$1.4 \cdot M_\odot$ (mass) and $r_0 = 30$ km (radius) we obtained $P_B = 9L_\odot$ (bremsheat production) and $\nu = 3.5 \cdot 10^2\ \mathrm{s}^{-1}$ (rotational frequency). For the special quasar values $M^{(N)} = 10^8 \cdot M_\odot$ (mass) and $r_0 = 10^{16}$ cm (radius) follows $P_B = 1.38 \cdot 10^7 L_\odot$ and $\nu = 0.58\ \mathrm{y}^{-1}$.

In order to avoid misunderstandings we emphasize: By presenting the numerical evaluation of some theoretical conclusions of our theory we do not claim that the mechanisms of astrophysical effects considered here explain the full empirical experience. For illumination of this situation a further detailed study of the subject is essential. Nevertheless our predicted bremsheat production could be interesting for the energy balance of astrophysical bodies, e.g.with respect to volcanicity, plate tectonics and seismicity.

9. Thermal expansion of a sphere-like cosmic object

9.1. GENERAL THEORY

The idea of this section is to study the thermal heat expansion of a sphere-like cosmic object induced by the bremsheat production investigated in the previous section [12].

As it is well known, the differential formula for the linear thermal dilation of a rod is given by

$$\mathrm{d}\ell = \alpha_\ell \ell \mathrm{d}T \tag{122}$$

(ℓ length of the rod, T temperature, α_ℓ linear thermal coefficient of dilation). Using the formula (V volume of the sphere with the radius r)

$$\text{a)}\quad V = \frac{4\pi}{3} r^3 \quad \text{with} \quad \text{b)}\ \mathrm{dV} = 4\pi \mathrm{r}^2 \mathrm{dr}\,, \tag{123}$$

one finds for the differential dilations

$$\text{a)}\ \mathrm{d}r = \alpha_\ell\, r\, \mathrm{d}T, \quad \text{b)}\ \mathrm{d}V = \alpha_c V \mathrm{d}T, \tag{124}$$

where $\alpha_c = 3\alpha_\ell$ is the cubic thermal coefficient of dilation.

For later application we need the relationship between the heat content Q and the temperature T of a body of the mass M. The well-known formula reads (c_Q specific heat)

$$\frac{\mathrm{d}Q}{\mathrm{d}t} = c_Q M \frac{\mathrm{d}T}{\mathrm{d}t}\,. \tag{125}$$

Let us now perform a rough global treatment of the problem posed in order the get some estimates on the expansion process of the body considered.

Our basic idea is such that the scalaric cosmological bremsheat production leads to two main effects: release of thermal radiation and increase of the temperature of the body, i.e. expansion of the body. For this reason we physically identify up to a free individual factor f_S the quantities (125) and (98):

$$\frac{\mathrm{d}Q}{\mathrm{d}t} = -f_S \frac{\mathrm{d}Q_B}{\mathrm{d}t}. \tag{126}$$

The "heat consumption factor" f_S describes the portion of the scalaric bremsheat which is used for the dilation of the volume of the body. Then from (125) we get

$$\frac{\mathrm{d}T}{\mathrm{d}t} = -\frac{f_S}{Mc_Q}\frac{\mathrm{d}Q_B}{\mathrm{d}t}. \tag{127}$$

Eliminating by means of (124a) leads to the temporal change of the radius of the sphere:

$$\frac{\mathrm{d}r}{\mathrm{d}t} = -\frac{f_S\,\alpha_\ell\, r}{Mc_Q}\frac{\mathrm{d}Q_B}{\mathrm{d}t}. \tag{128}$$

For later application it is convenient to introduce the "scalaric material factor" of the body

$$\Sigma_S = \frac{f_S\,\alpha_\ell}{c_Q}. \tag{129}$$

Then by means of (98)and (101) we get from (128)

$$\frac{\mathrm{d}r}{\mathrm{d}t} = \frac{\Sigma_S\, r}{M}\left[M\dot{\boldsymbol{r}}_c^2 + \sum_{a,b=1}^{3} I_{ab}\,\omega_a\omega_b\right]\frac{\mathrm{d}\ln\sigma}{\mathrm{d}t}. \tag{130}$$

If the translational effect considerably dominates the rotational one, which for cosmic bodies within our planetary system is the case, the latter formula reduces to

$$\frac{\mathrm{d}r}{\mathrm{d}t} = \Sigma_S r\dot{\boldsymbol{r}}_c^2\frac{\mathrm{d}\ln\sigma}{\mathrm{d}t}. \tag{131}$$

From (130) or (131) we learn that the relative scalaric thermal expansion effect of a body is independent of the mass of the body, i.e. this effect is a universal cosmological effect.

9.2. THERMAL EXPANSION OF A BODY ORBITING ABOUT A CENTRAL MASS

Now we apply the result (131) to a body moving approximately on a circular orbit with the radius R_S. According to our theory in this case the formula

$$\dot{\boldsymbol{r}}_c^2 = \frac{\gamma_N M_c^{(S)}}{R_S} \tag{132}$$

is valid, where $M_c^{(S)}$ (72) is the gravitative mass of the central body. Eliminating in (131) gives the general relation

$$\frac{\mathrm{d}r}{\mathrm{d}t} = \frac{\gamma_N M_c^{(S)}\Sigma_S\, r}{R_S}\frac{\mathrm{d}\ln\sigma}{\mathrm{d}t}. \tag{133}$$

One should remember that for the present time $M_{c|p}^{(S)} = M_c^{(N)}$ (usual Newtonian mass) is valid.

To investigate the long-time course of the radius of the spherical cosmic object we have to integrate (133). For this reason we first rearrange it by means of (72):

$$\frac{\mathrm{d}\ln r}{\mathrm{d}t} = \Sigma_S \left(\frac{\gamma_N \mathcal{M}_c}{F_0}\right)^2 \frac{(\sigma^2-1)^2}{\sigma} \frac{\mathrm{d}\sigma}{\mathrm{d}t}. \tag{134}$$

Referring to the case of validity of the inequality $\sigma^2 \gg 1$ being fulfilled for the time of about 1000 y after the big start and later, i.e. valid at the time of birth of cosmic objects. Therefore we are allowed to go over from (134) to

$$\frac{\mathrm{d}\ln r}{\mathrm{d}t} = \frac{1}{4}\,\Sigma_S \left(\frac{\gamma_N \mathcal{M}_c}{F_0}\right)^2 \frac{\mathrm{d}\sigma^4}{\mathrm{d}t}. \tag{135}$$

Now it is convenient to introduce the "scalaric cosmic expansion factor"

$$E_S = \frac{1}{4}\,\Sigma_S \left(\frac{\gamma_N \mathcal{M}_c}{F_0}\right)^2. \tag{136}$$

Then (135) reads

$$\frac{\mathrm{d}\ln r}{\mathrm{d}t} = E_S \frac{\mathrm{d}\sigma^4}{\mathrm{d}t}. \tag{137}$$

Let us further assume that this factor may be a constant: E_S=const.

Now we are able to integrate with the result

$$r = \bar{r} \exp\left(E_S\,\sigma^4\right) \tag{138}$$

($\bar{r}$ constant of integration). For practical use it is comfortable to write this equation in the form

$$r = r_b \exp\left[E_S\left(\sigma^4 - \sigma_b^4\right)\right], \tag{139}$$

where

$$\text{a)}\quad r_b = r(t=t_b) \quad \text{and} \quad \text{b)}\quad \sigma_b = \sigma(t=t_b) \tag{140}$$

mean the values of the radius of the sphere and of the scalaric world function at the time of birth of the cosmic object considered (index b refers to birth). By rearranging (137) we find the corresponding formula for the expansion velocity of the sphere:

$$\frac{\mathrm{d}r}{\mathrm{d}t} = 4\,E_S\,r\,\sigma^3\,\frac{\mathrm{d}\sigma}{\mathrm{d}t}. \tag{141}$$

9.3. SOME GLOBAL NUMERICAL RESULTS FOR AN EARTH-LIKE MODEL

Let us start with some historical annotations: For a long time geophysicists have discussed the history of the evolution of the earth, particularly also the problem of

contraction or expansion. In the first period of research the opinion of a contracting earth strongly dominated. In context with A. Wegener's hypothesis of continental drift (1915) the idea of an expanding earth won followers as O. C. Hilgenberg (1933), V. B. Nejman (1962), S. W. Carey (1976), J. Koziar (1980), N. J. Osipisin and V. F. Blinov (1987), G. O. W. Kremp (1992) and many others. Nevertheless in spite of all scientific activities the supporters of this concept form a small minority.

With respect to a theoretical foundation of the concept of an expanding earth we remind of P. Jordan (1955) who followed P. A. M. Dirac's idea (1938) of a decreasing "gravitational constant" in the course of time. The theories of Jordan and some other theoreticians came in contradiction particularly to the Einstein effects within our planetary system. The reason for our present treatise is to show that our PUFT, which is in agreement with the Einstein effects, leads to some predictions which could be interesting for astrophysicists and geophysicists. Therefore we hope that our new astrophysical and geophysical effects (if they exist at all) will be taken into account among the large variety of effects being under investigation.

In comparing our results with the geophysical experience we get some help by the empirical exponential Koziar formula (1994) on the expansion of the earth [13]:

$$r = r_1 + r_2\, \mathrm{e}^{\varrho t}, \tag{142}$$

where $r_1 = 2800$ km, $r_2 = 3570$ km, $\varrho = 7.25 \cdot 10^{-9}\ \mathrm{y}^{-1}$. From this formula the present velocity of expansion of the earth (surface)

$$\left(\frac{\mathrm{d}r}{\mathrm{d}t}\right)_p = 2.6\ \mathrm{cm\ y}^{-1} \tag{143}$$

results. But we mention that other geophysicists (e.g. L. Egyed) take into consideration the considerably smaller value

$$\left(\frac{\mathrm{d}r}{\mathrm{d}t}\right)_p \approx 5\ (10^{-2}\ \text{to}\ 10^{-1})\ \mathrm{cm\ y}^{-1}\,. \tag{144}$$

Let us in the sense of a rough estimate now exploit the formulas (139) and (141). First we are able to calculate the quantity $(\gamma_N \mathcal{M}_c/F_0)^2$, since we know the data

$$\text{a)}\quad M_c^{(N)} = 1.989 \cdot 10^{33}\ \mathrm{g} \quad \text{(mass of the sun)}\,, \tag{145}$$

$$\text{b)}\ |\, \boldsymbol{r} \times \dot{\boldsymbol{r}}\, | = 4.46 \cdot 10^{19}\ \mathrm{cm^2\ s^{-1}} \quad \text{(areal velocity of the earth)}\,.$$

Remembering the values $\sigma_p = 59.7731$ and $(\frac{\mathrm{d}\sigma}{\mathrm{d}t})_p = 9.48 \cdot 10^{-10}\ \mathrm{y}^{-1}$ (51), with the help of (145a) and (72) we find

$$\text{a)}\quad \mathcal{M}_c = 3.3 \cdot 10^{31}\ \mathrm{g}\,, \quad \text{b)}\quad \mathrm{F}_0 = 2.66 \cdot 10^{21}\ \mathrm{cm^2\ s^{-1}}. \tag{146}$$

Thus we arrive at

$$\left(\frac{\gamma_N \mathcal{M}_c}{F_0}\right)^2 = 6.96 \cdot 10^5\ \mathrm{cm^2\ s^{-2}}. \tag{147}$$

Applying this result to (136) we get

$$E_S = 1.74 \cdot \Sigma_S \cdot 10^5 \text{ cm}^2 \text{ s}^{-2}. \tag{148}$$

Decisive for the following is now some knowledge about the parameter Σ_S (129) in which the linear thermal coefficient of dilation α_ℓ and the specific heat c_Q occur.

In new geophysical literature on the earth one finds the average values [14]

$$\text{a)} \quad \alpha_\ell = 2.28 \cdot 10^{-5} \text{ K}^{-1}, \quad \text{b)} \quad c_Q = 1.5 \cdot 10^7 \text{ cm}^2\text{s}^{-2}\text{K}^{-1}. \tag{149}$$

If we use for the heat consumption factor the rough value $f_S = 0.5$, we obtain from (129)

$$\Sigma_S = 7.6 \cdot 10^{-13} \text{ cm}^{-2}\text{s}^2 \tag{150}$$

and further from (148)

$$E_S = 1.32 \cdot 10^{-7} \,. \tag{151}$$

If we take for the age of the earth (with an open value of the radius at birth) the value $(\triangle t)_e = 4.6 \cdot 10^9$ y, then the birth of the earth took place in $t_b = 14.4 \cdot 10^9$ y after the big start (Urstart). For the scalaric world function at this time the value $\sigma_b = 51.64$ and ${\sigma_b}^4 = 7.11 \cdot 10^6$ (numerical results) holds. Applying these results to (139) we arrive at

$$\text{a)} \quad \frac{r}{r_b} = \exp\left[1.32 \cdot 10^{-7}\left(\sigma^4 - 7.11 \cdot 10^6\right)\right], \quad \text{b)} \quad \frac{r_p}{r_b} = 2.12. \tag{152}$$

Let us next apply (141) to the present time:

$$\left(\frac{\mathrm{d}r}{\mathrm{d}t}\right)_p = 4E_S\, r_p\, \sigma_p^3 \left(\frac{\mathrm{d}\sigma}{\mathrm{d}t}\right)_p . \tag{153}$$

Inserting the values $r_p = 6371$ km (present radius of the earth) and further the result (151), we get for the expansion velocity of the earth (surface)

$$\left(\frac{\mathrm{d}r}{\mathrm{d}t}\right)_p = 6.8 \cdot 10^{-2} \text{ cm y}^{-1}. \tag{154}$$

Thanks to the immense progress in superconductivity and laser physics nowadays such an extreme precision in length measuring technique was reached that it is possible to measure an expansion of the earth of about 1 cm per year and better. We hope that this technical development can help to decide soon the question after the expansion of the earth.

Similar calculations have been performed for moon, Mars and Jupiter.

For plotting of the temporal course of the radius and the radial velocity we annotate: The abscissa of the figures presented in the following refers to the rescaled time $\eta = 0.945 \cdot 10^{-9} t\, \text{y}^{-1}$. As mentioned above this practically means that the unit $\Delta\eta = 1$ roughly corresponds to 10^9 y. Referring to the figures for the radius,

Figure 5. Temporal course of the radius of an earth-like cosmic object

Figure 6. Temporal course of the radial velocity of an earth-like cosmic object

the unit of the radius at the ordinate is given in cm; referring to the figures for the velocity, the unit of the velocity at the ordinate is $\mathrm{cm/y}$.

The temporal course of the radius of the spherical body is presented in Fig. 5 for the whole time scale since the big start. The temporal course of the radial velocity of the surface of the spherical body is presented in Fig. 6 which shows the course of the velocity for the whole time scale since the big start.

10. Some global numerical results for a star-like cosmic object (Sun as a model)

10.1. PRELIMINARY CONSIDERATIONS

These days it is generally recognized in science that, as the Sun burns through its hydrogen on the main sequence, it steadily grows hotter and therefore more luminous. It is also accepted that through this fact the Sun continuously grows larger. Recently an interesting paper on this subject has been distributed by Korycansky et al. [15].

For rough application of the theory presented above we refer to approximate numerical values of the Sun as a numerical model (further short: sun) orbiting about the center of the Galaxy):

$$\begin{aligned}
&\text{a)}\quad R &&= 2.6\cdot 10^{22}\,\mathrm{cm} && \text{(radius of the orbit)},\\
&\text{b)}\quad V &&= 2.2\cdot 10^{7}\,\mathrm{cm\,s^{-1}} && \text{(orbital velocity of the sun)},\\
&\text{c)}\quad M_c &&= 1.8\cdot 10^{44}\,\mathrm{g} && \text{(acting mass of the Galaxy)},\\
&\text{d)}\quad r_p &&= 6.96\cdot 10^{10}\,\mathrm{cm} && \text{(present radius of the sun)},\\
&\text{e)}\quad t_{sun} &&= 4.66\cdot 10^{9}\,\mathrm{y} && \text{(age of the sun)}.
\end{aligned} \tag{155}$$

Let us mention that the value of the central mass acting at the place of the sun resulted from our theory of the rotation curve [16]. Obviously this value is different from the usually accepted value of the mass of the whole Galaxy which is somewhat greater.

By means of the above values we find for the sun

$$F_0 = 3.46 \cdot 10^{31}\,\mathrm{cm}^2\,\mathrm{s}^{-1}\,. \tag{156}$$

The main problem arising now is to find a way to get information on the scalaric expansion factor E_S of the sun. For comparing it is appropriate to remember the results obtained for planet-like cosmic bodies (151).

The situation with respect to the sun is insofar qualitatively different from the situation just mentioned, since the interior of the sun consists of gas (mainly H, partly atomic burning to He) with a very high temperature. For simplicity we approximately treat this problem by referring to a perfect gas for which the relation

$$\overline{\varepsilon} = \frac{m_0}{2}\,\overline{u^2} = \frac{3\mathrm{k}T}{2} \tag{157}$$

is valid (m_0 mass of a gas particle, u velocity of the gas particles subjected to averaging, k Boltzmann constant, T kinetic temperature). As it is well known, for a perfect gas the formulas

$$\text{a)}\quad \alpha_c = \frac{1}{T} = \frac{3\mathrm{k}}{m_0\overline{u^2}}\,, \qquad \text{b)}\quad c_Q = \frac{3\mathrm{k}}{2m_0} \tag{158}$$

hold. Hence the relations (129) and (136) take the form

$$\Sigma_S = \frac{2f_S m_0}{3\mathrm{k}T} \tag{159}$$

and

$$E_S = \frac{f_S m_0}{6\mathrm{k}T}\left(\frac{\gamma_N M_c}{\sigma F_0}\right)^2 . \tag{160}$$

Using the numerical values (155) and (156) for the sun, we find

$$\text{a)}\quad \left(\frac{\gamma_N M_c}{\sigma F_0}\right)^2 = 3.38 \cdot 10^7\,\mathrm{cm}^2\,\mathrm{s}^{-2} \quad \text{and} \quad \text{b)}\quad \Sigma_S = 8.12 \cdot 10^{-16}\,\mathrm{cm}^{-2}\,\mathrm{s}^2. \tag{161}$$

As mentioned above, it is our aim to treat cosmic bodies globally. Therefore it seems to be acceptable to take the value $T = 5 \cdot 10^6\,\mathrm{K}$ as an appropriate mean value of the kinetic temperature of the sun. Let us further remember the value of the Boltzmann constant $\mathrm{k} = 1.38 \cdot 10^{-16}\,\mathrm{g\,cm^2 s^{-2}\,K^{-1}}$ and the value of the proton mass $m_p = 1.68 \cdot 10^{-24}\,\mathrm{g}$ (being used as the mass of the H-atom constituent of the gas considered). Hence we obtain from (160) the numerical result ($f_S = 1$)

$$E_S = 6.865 \cdot 10^{-9}\,. \tag{162}$$

10.2. NUMERICAL EVALUATION AND PLOTTING FOR THE SUN (AS A MODEL)

10.2.1. *Numerical formulas for radius and expansion velocity*

Inserting the values (162), (155d) and (51f, g) into formula (153), we find for the present expansion radial velocity of the surface of the sun

$$\left(\frac{\mathrm{d}r}{\mathrm{d}t}\right)_p = 0.387\,\mathrm{cm\,y^{-1}}\,. \tag{163}$$

Further we get information from formula (139) on the temporal behavior of the radius of the sun. Inserting (162) into this equation we arrive at

$$r_p = r_b \exp[6.865 \cdot 10^{-9}(\sigma_p^4 - \sigma_b^4)]\,. \tag{164}$$

Now from (155d) we know the quantity r_p and from (51f) the quantity σ_p. As mentioned above, there is a good consensus among astrophysicists that the age of the sun is about 4.66 billion years. Therefore we need the value of σ at the time of birth of the sun. Since the ages of the sun and the earth approximately coincide, we can take over the values applied above for the earth: $\sigma_b = \sigma(t = t_b) = 51.64$ and $\sigma_b^4 = 7.11 \cdot 10^6$.

Now we are prepared to calculate the radius of the sun at the birth with the result

$$r_b = 6.695 \cdot 10^{10}\mathrm{cm}\,. \tag{165}$$

10.2.2. *Annotation to the mass of the Galaxy*

In investigating the orbital motion of the sun about the central body of the Galaxy, for physical reasons it is necessary to use the gravitational force just at the place of the moving sun. Because of the matter (particularly dark matter) outside the sun it is obvious that the mass causing the gravitational force mentioned is not the total mass of the Galaxy. We recently treated the problem of the radial mass distribution in the Galaxy within the framework of our theory of the rotation curve of stars [16]. In that paper we came to the numerical value (155c) of the gravitationally acting mass at the place of the sun. All numerical calculations performed above are based on this value.

From formula (160) we learn that the scalaric cosmic expansion factor E_S contains M_c quadratically. That means under the circumstances of the exponential character of the expansion law (139) an extraordinary sensitivity of the radius on the mass M_c.

Let us conclude these considerations with the general remark that the curves show a quasi-continuous course through the whole time scale from near the big start to the presence, i.e. there is no hint at the time of birth of the cosmic object considered. All in all it seems that this theory corresponds to a evolution of the star-like cosmic objects from "small to large" and not according to the accretion concept from "large to small".

11. Theory of dark matter accretion around a center

Empirical astrophysical estimates of the visible mass density of the normal (mostly baryonic) matter come to the maximum value $\approx 10^{-30}$ g cm^{-3}. We interpreted our cosmological result shown above with respect to this difference in the mass densities as a hint at the existence of a dominating dark matter part with a mass density more than two orders of magnitude greater than that of the normal matter. Our theory of dark matter accretion around a gravitating central body is presented in paper [17].

Our hypothetical model of the cosmos investigated, roughly corresponds to the following picture of the present cosmos: Our cosmos consists of a gas of dark matter particles (dm-particles) penetrating all matter of the cosmos, particularly also the existing compact objects (stars, nuclei of galaxies etc.) which look like buoys in the dark matter sea. Assuming a homogeneous gas of one sort of particles, by some hypothetical arguments we recently were led to the following hypothetical numerical values:

$$\begin{aligned} \text{a) } m_p &= 2 \cdot 10^{-36}\text{g} = 1.13 \cdot 10^{-3}\text{eV/c}^2 \quad \text{(rest mass of the dm-particle)}, \\ \text{b) } T_p &= 1.7\,\text{K} \quad \text{(kinetic temperature of the dm-gas)}. \end{aligned} \tag{166}$$

As a result of the attractive interaction of the dm-particles with the compact object considered we expect a statistical distribution of the dm-particles within and around the compact object being embedded in this dm-gas. Let us introduce the notion "accretion cloud" (Umwolke) for this part of the dm-gas which by accretion exceeds the cosmological average distribution of the dm-gas. For simplicity we model the compact object by a homogeneous mass sphere. Further for simplicity we apply the Boltzmann-Maxwell statistics describing spinless particles without degeneracy.

Let us here mention that in a different context and on a different theoretical basis H. Dehnen et al. [18] used the Bose-Einstein statistics (preferred by physical arguments) and the Fermi-Dirac statistics (dropped) in treating the dark matter in galaxies in order to find a theoretical concept in understanding the problem of the "flat rotation curves" of stars in galaxies. In interesting papers detailed quantum-statistical calculations were performed. We think that for a rough understanding of our approach it is legitimate to simplify the situation by referring to the Boltzmann-Maxwell statistics.

11.1. BASIC EQUATIONS

In the subsection 5.2 we treated the non-relativistic weak field approximation of the PUFT field equations for a point-like central body. In the following these field equations are specialized to the non-relativistic and weak field case for a continuous matter distribution, particularly around a sphere-like body. Then the gravita-

tional field equation is given by

$$\Delta\Phi = 4\pi\gamma_N\mu \tag{167}$$

($\Phi(\boldsymbol{r},t)$ local Newtonian gravitational field, $\mu(\boldsymbol{r},t)$ mass density).

In this approximation the scalaric field may consist of two parts according to

$$\text{a)}\quad \sigma = \sigma_c + s \quad \text{with} \quad \text{b)}\ |s| \ll |\sigma_c|\ , \tag{168}$$

where $\sigma_c(t)$ is the global scalaric cosmological field and $s(\boldsymbol{r},t)$ the local scalaric field of the central body. Then the scalaric field equation reads

$$\Delta\sigma = \Delta s = -\frac{4\pi\gamma_N\mu}{\sigma_c c^2}. \tag{169}$$

In the general case of a test body moving in the external fields Φ and s as well as in eventually existing external electromagnetic fields (neglecting in all fields the back reaction) the equation of motion reads:

$$M\left(\frac{\mathrm{d}\boldsymbol{v}}{\mathrm{d}t} + \operatorname{grad}\Phi + \frac{c^2}{\sigma_c}\operatorname{grad} s + \boldsymbol{v}\frac{\mathrm{d}\ln\sigma}{\mathrm{d}t}\right) = Q\left(\boldsymbol{E} + \frac{\boldsymbol{v}\times\boldsymbol{B}}{c}\right)\ . \tag{170}$$

The special case of a point-like central body has been presented in equation (70).

In the following we refer to a test body without electric charge, i.e. $Q = 0$. Because of the same mathematical structure of both the equations (169) and (167), in this approximation it is possible to introduce the combined field function

$$\Psi = \Phi\left(1 - \frac{1}{\sigma_c^2}\right) + c^2\ln\sigma_c + \frac{1}{\sigma_c^2}\Phi_c \tag{171}$$

($\Phi_c(t)$ cosmological value of the Newtonian potential). Hence we obtain the common field equation

$$\Delta\Psi = 4\pi\gamma_N\left(1 - \frac{1}{\sigma_c^2}\right)\mu \tag{172}$$

and the equation of motion

$$\frac{\mathrm{d}\boldsymbol{v}}{\mathrm{d}t} + \operatorname{grad}\Psi + \boldsymbol{v}\frac{\mathrm{d}\ln\sigma}{\mathrm{d}t} = 0. \tag{173}$$

Let us now use following notation:

$$\mu = \mu_n + \mu_{dm} \tag{174}$$

(μ_n mass density of normal matter, μ_{dm} mass density of dark matter). Application of this latter formula to the interior (i) and to the exterior (e) of the spherical central body leads to the equations

$$\text{a)}\quad \mu_i = \mu_{ni} + \mu_{dmi} \quad \text{and} \quad \text{b)}\quad \mu_e = \mu_{ne} + \mu_{dme}\ . \tag{175}$$

Next we split the mass densities into both the parts coming from the global cosmological matter (normal matter and dm-matter) and from the local matter (central body and accretion cloud):

$$\text{a)}\quad \mu_{ni} = \mu_{ng} + \mu_{ns}, \qquad \text{b)}\quad \mu_{dmi} = \mu_{dmg} + \hat{\mu}_{dmi} \tag{176}$$

and

$$\text{a)}\quad \mu_{ne} = \mu_{ng}\,, \qquad \text{b)}\quad \mu_{dme} = \mu_{dmg} + \hat{\mu}_{dme}\,. \tag{177}$$

Here the indices refer to: $g \to$ global (cosmological contribution) and $s \to$ sphere (central body contribution). The roof denotes the dm- contribution induced by the central body, i.e. surplus dark matter to be treated statistically.

For our further calculations it is convenient to introduce the abbreviations

$$\begin{aligned} &\text{a)}\quad \widetilde{\mu}_e = \mu_G + \hat{\mu}_{dme} \quad \text{with} \quad \text{b)}\quad \mu_G = \mu_{ng} + \mu_{dmg}, \quad \text{i.e.} \\ &\text{c)}\quad \mu_i = \mu_G + \mu_{ns} + \hat{\mu}_{dmi}\,. \end{aligned} \tag{178}$$

Let us remind that our cosmological model led us to following numerical values of the scalaric cosmological world function:

$$\begin{aligned} &\text{a)}\quad \sigma_c(t \approx 1000\ \text{y}) \approx 3.3\,, \quad \text{b)}\quad \sigma_{cp} = 59.7731\,, \quad \text{i.e.} \\ &\text{c)}\quad \sigma_c^2 \gg 1 \quad \text{(for the time scale under consideration).} \end{aligned} \tag{179}$$

Then the field equation (172) for the interior and exterior reads:

$$\text{a)}\quad \Delta\Psi_i = 4\pi\gamma_N\mu_i, \quad \text{b)}\quad \Delta\Psi_e = 4\pi\gamma_N\widetilde{\mu}_e. \tag{180}$$

Further from (171) results

$$\Psi = \Phi + c^2 \ln \sigma_c\,. \tag{181}$$

Next, analogously to the above formulas for the mass density of the dm-particles we now write down the corresponding formulas for the particle number density n_{dm} being related to the mass density as follows (m mass of a dm-particle):

$$\text{a)}\quad \mu_{dm} = m n_{dm}\,, \quad \text{b)}\quad \mu_{dmg} = m n_{dmg}\,, \quad \text{c)}\quad \hat{\mu}_{dm} = m\hat{n}_{dm}\,. \tag{182}$$

We find

$$n_{dm} = n_{dmg} + \hat{n}_{dm}\,. \tag{183}$$

In (182) and (183) we omitted the indices i and e.

Since the time dependence of the cosmological quantities (e.g. of $\sigma_c(t)$) is extremely slow (adiabatic time dependence), compared with the time dependence of the cosmogonic processes of the cosmic objects, we omit explicit writing of the time t in such cosmological quantities. Particularly constants of spatial integration implicitly involve this adiabatic time dependence.

11.2. STATISTICAL DM-PARTICLE DISTRIBUTION IN THE ACCRETION CLOUD

According to our accretion concept the statistical dm-particle number density for the case of spherical symmetry reads:

$$n \equiv \hat{n}_{dm} = \bar{n}\left[\exp\left(-\frac{m\chi(r)}{kT}\right) - 1\right], \tag{184}$$

where $\bar{n}$ denotes the dm-particle number density far away from the cental body:

$$\text{a)} \quad \bar{n} = n(r=\infty) \quad \text{with} \quad \text{b)} \quad \chi_\infty \equiv \chi_e(r=\infty) = 0\,. \tag{185}$$

The potential function χ used is related to Ψ by

$$\text{a)} \quad \Psi = \chi + \Psi_c\,, \quad \text{where} \quad \text{b)} \quad \Psi_c = \Phi_c + c^2 \ln \sigma_c\,. \tag{186}$$

Using (184) we can write the equations (180) as

$$\begin{aligned} \text{a)} \quad \Delta\chi_i &= 4\pi\gamma_N\left[\mu_0 + m\bar{n}\left\{\exp(-\tfrac{m\chi_i}{kT}) - 1\right\}\right], \\ \text{b)} \quad \Delta\chi_e &= 4\pi\gamma_N\left[\mu_G + m\bar{n}\left\{\exp(-\tfrac{m\chi_e}{kT}) - 1\right\}\right], \end{aligned} \tag{187}$$

where the quantity

$$\mu_0 = \mu_G + \mu_{ns} = \text{const} \tag{188}$$

(referring to a homogeneous sphere with radius r_0) means the mass density of the sphere.

Let us for the following use the approximation assumption

$$\left|\frac{m\chi}{kT}\right| \ll 1 \tag{189}$$

being well fulfilled in our further applications. Hence series expansion of (184) leads to the linearity

$$n = -\frac{\bar{n}m\chi}{kT} \tag{190}$$

between n and χ. This simplification means that we are able to perform the further calculations analytically. Then the equations (187) commonly treated (omitting the indices i and e) read

$$\Delta\chi + \varkappa^2\chi = 4\pi\gamma_N\hat{\mu}\,, \tag{191}$$

where $\hat{\mu}$ means μ_0 for the interior and μ_G for the exterior, and $\varkappa^2$ is defined by

$$\varkappa^2 = \frac{4\pi\gamma_N m^2\bar{n}}{kT}\,. \tag{192}$$

Let us here mention that the author's dissertation had referred to the theory of strong electrolytes, where according to the Debye-Milner theory the statistical

treatment of a (negative) ion cloud around a fixed (positive) ion (and vice versa) plays an important role. This knowledge induced the author's idea to treat the dark matter gas analogously. But in the first moment he was surprised that, though attractive forces act between positive and negative electric charges as well as between masses, in his basic equation (191) the second term on the left hand side appeared with a positive sign, in contrast to the theory of strong electrolytes. The consequence of this fact is that in the Debye-Milner theory a Yukawa-like term with exponential decrease occurs, whereas in this theory an interesting phenomenon of periodicity is met.

In solving the equation (191) we first go over to spherical polar coordinates:

$$\frac{\mathrm{d}}{\mathrm{d}r}\left(r^2\frac{\mathrm{d}\chi}{\mathrm{d}r}\right) + \varkappa^2 r^2 \chi = 4\pi\gamma_N \hat{\mu} r^2 . \tag{193}$$

In performing the further calculations being presented in detail in [17] we realized that following basic functions play an important role:

$$\text{a)}\quad U(z) = z\sin z + \cos z \quad \text{and} \quad \text{b)}\ V(z) = \sin z - z\cos z . \tag{194}$$

Finally we arrived at following results:

$$\begin{aligned} &\text{a)}\quad \chi_i = B_0\left\{1 - \frac{1}{\varkappa r}U(\varkappa r_0)\sin(\varkappa r)\right\} , \\ &\text{b)}\quad \frac{\mathrm{d}\chi_i}{\mathrm{d}r} = \frac{B_0}{\varkappa r^2}U(\varkappa r_0)V(\varkappa r) ; \end{aligned} \tag{195}$$

$$\begin{aligned} &\text{a)}\quad \chi_e = -\frac{B_0}{\varkappa r}V(\varkappa r_0)\cos(\varkappa r) , \\ &\text{b)}\quad \frac{\mathrm{d}\chi_e}{\mathrm{d}r} = \frac{B_0}{\varkappa r^2}V(\varkappa r_0)U(\varkappa r) , \end{aligned} \tag{196}$$

where

$$\text{a)}\quad B_0 = \frac{\mu_0 \mathrm{k}T}{m^2\bar{n}} = \frac{3\gamma_N M_c}{\varkappa^2 r_0^3} \quad \text{with} \quad \text{b)}\ M_c = \frac{4\pi\mu_0 r_0^3}{3} \tag{197}$$

(M_c mass of the sphere) holds.

11.3. RADIAL DRIFT OF A TEST BODY ("PIONEER EFFECT")

Recent evaluation of radio metric data from Pioneer 10/11, Galileo and Ulysses spacecraft by Anderson et al. [19] indicates an anomalous, constant acceleration acting on the spacecraft, being about 50 AU far from the Sun, with a magnitude $\approx 8.5\cdot 10^{-8}\mathrm{cm/s}^2$, directed towards the Sun. Apparently the explanation of this new effect seems to be related to a correction of Newtonian mechanics by additional

terms. In the following we try to find an explanation of this radial drift effect by applying our theory.

The equation of motion of a test body (173) with the help of (186a) takes the form

$$\frac{\mathrm{d}\boldsymbol{v}}{\mathrm{d}t} + \mathrm{grad}\chi + \boldsymbol{v}\frac{\mathrm{d}\ln\sigma_c}{\mathrm{d}t} = 0\,. \tag{198}$$

From this equation we learn that for a spherically symmetric potential, as investigated above, the appearing acceleration A of the body considered can be split into the Newtonian part A_N and the scalaric part A_S according to

$$A = \frac{\mathrm{d}\chi}{\mathrm{d}r} = A_N + A_S\,. \tag{199}$$

Referring to the interior and exterior of the central body we identify

$$\text{a)}\quad A_{Ni} = \frac{\gamma_N M_c r}{r_0^3} \quad \text{and} \quad \text{b)}\quad A_{Ne} = \frac{\gamma_N M_c}{r^2} \tag{200}$$

(interior and exterior Newtonian accelerations). With the help of (195b) and (196b) the additional scalaric parts take the shape

$$\begin{aligned} A_{Si} &= \frac{\gamma_N M_c \varkappa^2}{(\varkappa r_0)^3}\left[\frac{3U(\varkappa r_0)V(\varkappa r)}{(\varkappa r)^2} - \varkappa r\right] \approx \frac{\gamma_N M_c \varkappa^2 r}{2r_0}\left[1 - \frac{1}{5}\left(\frac{r}{r_0}\right)^2\right], \\ A_{Se} &= \frac{\gamma_N M_c}{r^2}\left[\frac{3V(\varkappa r_0)U(\varkappa r)}{(\varkappa r_0)^3} - 1\right] \approx \frac{\gamma_N M_c \varkappa^2}{2}\left[1 - \frac{1}{4}(\varkappa r)^2\right]. \end{aligned} \tag{201}$$

Taking into account that the series expansion applied is valid for $(\varkappa r)^2 \ll 1$, we compare the latter formula with the empirical facts mentioned above:

$$\frac{\gamma_N M_c \varkappa^2}{2}\left[1 - \frac{1}{4}(\varkappa r)^2\right] = 8.5 \cdot 10^{-8}\,\mathrm{cm\,s^{-2}}\,. \tag{202}$$

Inserting the well-known values of the Newtonian gravitational constant, the mean distance of the spacecraft considered from the Sun ($r = 50$ AU), and the mass of the Sun ($M_c = 1.989 \cdot 10^{33}$ g), we arrive at the value of $\varkappa$ for the Sun (1 AU $= 1.496 \cdot 10^{13}$ cm)

$$\varkappa = 3.58 \cdot 10^{-17}\,\mathrm{cm}^{-1} = 5.36 \cdot 10^{-4}(\mathrm{AU})^{-1}\,. \tag{203}$$

Though our theory predicts a rather constant value of the radial acceleration far away from the Sun, nevertheless this acceleration value decreases weakly at greater distance.

12. Rotation curves of stars in galaxies

In a recent paper we applied our dark matter accretion theory presented in the previous section to the orbital motion of the stars around the center of the Galaxy

with the aim to find an explanation of the approximately flat rotation curves of the orbiting stars [16].

12.1. MOTION OF A TEST BODY IN POLAR COORDINATES

Starting point for our further studies is the equation of motion (198). Now we use the polar coordinates $\{R, \Phi\}$. Then after integration this equation reads (dot means derivative with respect to the time t)

$$\begin{aligned} &\text{a)} \quad \ddot{R} - R\dot{\Phi}^2 + \frac{\mathrm{d}\chi}{\mathrm{d}R} + \dot{R}\Sigma = 0, \\ &\text{b)} \quad R^2\dot{\Phi}\sigma_c = \mid \boldsymbol{R} \times \dot{\boldsymbol{R}} \mid \sigma_c = F_0 \quad \text{with} \\ &\text{c)} \quad \Sigma = \frac{\mathrm{d}\ln\sigma_c}{\mathrm{dt}}. \end{aligned} \tag{204}$$

As it is well known, the azimuthal velocity is defined by

$$v_\Phi = R\dot{\Phi} = \frac{F_0}{R\sigma_c}. \tag{205}$$

With the aid of this expression formula (204a) leads to

$$\ddot{R} - \frac{v_\Phi^2}{R} + \frac{\mathrm{d}\chi}{\mathrm{d}R} + \dot{R}\Sigma = 0. \tag{206}$$

Hence the equation

$$v_\Phi = \sqrt{R\ddot{R} + R\dot{R}\Sigma + R\frac{\mathrm{d}\chi}{\mathrm{d}R}} \tag{207}$$

follows. Now we introduce the abbreviation

$$A = \ddot{R} + \dot{R}\Sigma. \tag{208}$$

In the usual theory of the rotation curves on the basis of Newtonian mechanics approximately the motion of the body on a circle (R =const) is considered. We think this approximation is not good enough. Therefore, induced by the empirical situation for small values of the radial coordinate R we try the basic ansatz

$$A = \alpha R = 10^{-30} a R, \tag{209}$$

where α or a (the factor 10^{-30} is an adaption factor with respect to the large numerical astronomical values) are quantities to be specified by further concrete physical assumptions. Substituting this expression into (207) gives the formula for the so-called rotation curve $V = v_\Phi(R)$:

$$V = \sqrt{R\left(A + \frac{\mathrm{d}\chi}{\mathrm{d}R}\right)}. \tag{210}$$

Finishing this subsection we would like to emphasize that in our theory the situation is basically different to the usual theory of the rotation curves based on the assumption R =const, since here because of the periodicity occurring in the potential the expression $\frac{\mathrm{d}\chi}{\mathrm{d}R}$ is indefinite, i.e. that for $A = 0$ the radicand exhibits negative-valued regions.

12.2. ROTATION CURVE FOR THE EXTERIOR OF THE CENTRAL BODY IN GENERAL (AZIMUTHAL MOTION)

In our paper on rotation curves mentioned above [16] we treated the posed task in detail for the interior and exterior of the central body. Here we have to restrict to a short report for the exterior (index e). In this case with the help of (196b) and (209) equation (210) takes the shape

$$V_e = R\sqrt{\alpha_e + \frac{3\gamma_N M_c}{(\varkappa r_0)^3 R^3} V(\varkappa r_0) U(\varkappa R)}\,. \tag{211}$$

Analogously follows here the angular velocity

$$\omega_e = \frac{V_e}{R} = \sqrt{\alpha_e + \frac{3\gamma_N M_c}{(\varkappa r_0)^3 R^3} V(\varkappa r_0) U(\varkappa R)}\,. \tag{212}$$

12.3. PHYSICAL PROCESSES IN THE INTERIOR OF THE CENTRAL BODY (RADIAL MOTION)

Our next task is to get some information about the quantity A (208) by investigating physical main processes in the interior of the central body. We approach this problem tentatively by considering two opposite processes: 1. Expansion process of the central body by scalaric cosmological bremsheat production according to our hypothesis. 2. Scalaric-adiabatic cosmological contraction process according to our approximate treatment of the orbital motion of a test body considered.

12.3.1. *Expansion process (radial motion)*

Now it is convenient to introduce the scalaric-thermal velocity (bremsheat induced radial velocity). For this quantity we receive from (130) by means of (127)

$$v_{rQ} \equiv \frac{\mathrm{d}r_Q}{\mathrm{d}t} = \alpha_Q r\,, \tag{213}$$

where

a) $\alpha_Q = \dfrac{f_S J \alpha_c \Sigma}{3W}$ (scalaric-thermal velocity coefficient), (214)

b) $W = M_c c_Q$ (heat capacity of the central body with mass M_c) ,

c) $J = M_c \dot{r}_c^2 + \dfrac{2M_c}{5}(r_0\omega)^2$

is valid. Here one should remember that the coefficient α_Q as well as other cosmological quantities exhibit a slight scalaric-adiabatic cosmological time dependence.

12.3.2. *Scalaric-adiabatic contraction process (radial motion)*
Starting point is here the formulas (88a) and (90). As pointed out above, since about 1000 years after the big start the inequality $\sigma_c^2 \gg 1$ is well justified, i.e. both the equations mentioned read much simpler ($R_S \to r_S$):

$$\text{a)} \quad r_S = \frac{F_0^2}{\gamma_N \mathcal{M}_c {\sigma_c}^3}\,, \quad \text{b)} \quad \dot{r}_S = -\frac{3F_0^2}{\gamma_N \mathcal{M}_c {\sigma_c}^4}\dot{\sigma}_c\,. \tag{215}$$

By differentiation we find the expression

$$\ddot{r}_S = -\frac{3F_0^2}{\gamma_N \mathcal{M}_c {\sigma_c}^4}\left(\ddot{\sigma}_c - \frac{4}{\sigma}\dot{\sigma}_c^2\right)\,. \tag{216}$$

Substituting into the relation (208), being applied to this case, yields for the rearranged formula (209) the result

$$\alpha_S = \frac{A_S}{r_S} = -\frac{3}{\sigma_c}\left(\ddot{\sigma}_c - \frac{3}{\sigma_c}\dot{\sigma}_c^2\right)\,. \tag{217}$$

For eliminating the second order derivative of the scalaric field function σ_c we have to go back to the corresponding field equation contained in our publications mentioned above. After lengthy calculations one obtains

$$\mathrm{d}r_S = -3r\,\mathrm{d}\ln\sigma_c\,. \tag{218}$$

12.3.3. *Superposition of both radial effects*
In both preceding subsections we treated in detail the expansion effect and the contraction effect. By adding both effects we arrive at the total effect for the interior

$$\mathrm{d}r_i = \mathrm{d}r_Q + \mathrm{d}r_S\,. \tag{219}$$

Introducing the abbreviation

$$\tilde{\alpha} = \alpha_Q - 3\Sigma \tag{220}$$

leads to the relationship between the radius r and the total radial velocity

$$\dot{r}_i = \tilde{\alpha} r_i\,. \tag{221}$$

For further calculations it is convenient to use the scalaric bremsheat parameter

$$\beta_Q = \frac{J f_S \alpha_c}{3W}\,. \tag{222}$$

Then (214a) and (220) take the form

$$\text{a)} \quad \alpha_Q = \beta_Q \Sigma\,, \quad \text{b)} \quad \tilde{\alpha} = (\beta_Q - 3)\Sigma\,. \tag{223}$$

For the following we specialize our considerations to the case of a central body with a resting center of mass ($\dot{\boldsymbol{r}}_c = 0$). Then formula (214c) reduces to

$$J = \frac{2M_c}{5}(r_0\omega)^2\,. \tag{224}$$

Neglecting the scalaric-adiabatic time dependence of the material constitution quantity β_Q, then by differentiation of (221) we arrive at the relation

$$\ddot{r}_i = (\beta_Q - 3)\left[\dot{\Sigma} + (\beta_Q - 3)\Sigma^2\right] r_i\,. \tag{225}$$

Inserting the expressions (221) and (225) into the formula (208), applied to the interior ($R \to r_i$), leads to

$$A_i = \alpha_i r_i \tag{226}$$

with

$$\alpha_i = (\beta_Q - 3)\left[\dot{\Sigma} + (\beta_Q - 2)\,\Sigma^2\right]\,. \tag{227}$$

12.4. PHYSICAL PROCESSES IN THE EXTERIOR OF THE CENTRAL BODY (RADIAL MOTION)

The difference between the exterior and the interior consists in the fact that in the exterior no bremsheat effect takes place. This means that a moving body firstly, when leaving by jet the rotating central body, starts with the constant initial velocity

$$\dot{r}_{jet} = \dot{r}_Q(r = r_0) = \alpha_Q\, r_0\,, \tag{228}$$

and secondly underlies the scalaric-adiabatic cosmological contraction (218). Superposition of both effects gives

$$v_e \equiv \dot{r}_e = \alpha_Q r_0 - 3r\Sigma\,. \tag{229}$$

In this case from (208) follows

$$A_e = \ddot{r}_e + \dot{r}_e\Sigma = \alpha_e r\,, \tag{230}$$

where

$$\alpha_e = \Lambda - 3\Sigma^2 + \beta_Q\Sigma^2\frac{r_0}{r} \tag{231}$$

with

$$\Lambda = -3\left[\dot{\Sigma} - 3\Sigma^2\right] \tag{232}$$

holds.

12.5. ORBITAL MOTION OF A TEST BODY IN THE EXTERIOR OF THE CENTRAL BODY

12.5.1. *Rearrangement of the velocity equations in usual astronomical units*

In presenting the plots of the rotation curve and the spiral motion, in astrophysics the azimuthal velocity of the moving body (in astrophysics the notion "rotation velocity" is used) is indicated in $\frac{\text{km}}{\text{s}}$, whereas its distance from the central body is given in kpc. In adapting to this practice we have to rearrange the equations (211) and (229), using the relationship $1\text{kpc} = 3.086 \cdot 10^{16}$ km.The result of this recalculation is the following:

$$V_e = 30.86 \cdot \text{km} \cdot R \cdot (\text{kpc})^{-1} \sqrt{a_e + \frac{3\gamma_N M_c \cdot 10^{30}}{(\varkappa r_0)^3 R^3} V(\varkappa r_0) U(\varkappa R)} \tag{233}$$

and

$$v_e = 30.86 \cdot 10^{15} \cdot \text{km} \cdot [\alpha_Q r_0 - 3R\Sigma] \cdot (\text{kpc})^{-1} . \tag{234}$$

Both equations are the basis for our numerical investigations, particularly for plotting the rotation curve and the spiral, that will be done later.

12.5.2. *Spirality of the motion of the test body in the exterior*

The spiral form of the orbiting test body results by superposition of the radial velocity (234) and the azimuthal velocity (233). Let us introduce the notion "spirality" by the definition

$$Sp = \frac{V_e}{v_e} = \tan\chi , \tag{235}$$

where χ will be called spirality angle. Then the final formula for the spirality reads

$$Sp = \tan\chi = \frac{\sqrt{a_e + \frac{3\gamma_N M_c \cdot 10^{30}}{(\varkappa r_0)^3 R^3} V(\varkappa r_0) U(\varkappa R)}}{10^{15}\left(\alpha_Q \frac{r_0}{R} - 3\Sigma\right)} . \tag{236}$$

From this expression we learn that the reversion point of the radial motion is determined by the quantity

$$R_{rev} = \frac{\alpha_Q r_0}{3\Sigma} . \tag{237}$$

Remembering the relation

$$\text{a)} \quad v_e = \dot{R} \quad \text{and} \quad \text{b)} \quad V_e = R\dot{\Phi} \tag{238}$$

in polar coordinates, we arrive at the following relationship between the spiral angle χ and the polar angle Φ in form of the differential equation

$$\tan\chi = R\frac{\mathrm{d}\Phi}{\mathrm{d}R}, \tag{239}$$

where $\tan\chi$ is given by (236).

For our further calculations it is convenient to introduce the quantity $u = \varkappa R$. Then we arrive at the differential equation

$$\begin{aligned} \text{a)}\ \frac{\mathrm{d}\Phi}{\mathrm{d}u} &= \frac{1}{P}\sqrt{\alpha_S + \frac{A_Q\Sigma}{u} + \frac{Q_1 U(u)}{u^3}} \quad \text{with} \\ \text{b)}\ Q_1 &= \frac{3\gamma_N M_c V(\varkappa r_0)}{r_0^3},\ \text{c)}\ P = A_Q - 3u\Sigma,\ \text{d)}\ A_Q = \alpha_Q \varkappa r_0 . \end{aligned} \tag{240}$$

Integration leads to the implicit form $\Phi = \Phi(R)$ of the spiral equation (Φ_0 constant of integration, $u_0 = \varkappa r_0$) :

$$\Phi = \Phi_0 + \int\limits_{\xi=u_0}^{u} \frac{\sqrt{\alpha_S + \frac{A_Q\Sigma}{\xi} + \frac{Q_1 U(\xi)}{\xi^3}}}{A_Q - 3\xi\Sigma}\mathrm{d}\xi . \tag{241}$$

The intervals of the variables are given by

$$\text{a)}\ r_0 \leqq R \leqq R_{rev}, \quad \text{b)}\ u_0 \leqq u \leqq \varkappa R_{rev} . \tag{242}$$

For a better astrophysical understanding of the spiral function (241) and particularly for plotting we are forced to approximate this integral representation by series expansion about the expansion center u_0 according to $\xi = u_0 + \eta$. Expanding up to the second order in η, after a rather lengthy calculation we arrive at the result ($\frac{\eta}{u_0} \ll 1$)

$$\Phi - \Phi_0 = A_0\left[u - u_0 + \frac{N}{2}(u - u_0)^2\right], \tag{243}$$

where A_0 and N are defined by

$$\begin{aligned} \text{a)}\ A_0 &= \frac{1}{P_0}\sqrt{\alpha_S + \frac{A_Q\Sigma}{u_0} + \frac{Q_1 U(u_0)}{u_0^3}}, \\ \text{b)}\ N &= \frac{3\Sigma}{P_0} + \frac{-A_Q\Sigma u_0^2 + Q_1 u_0^2\cos u_0 - 3Q_1 U(u_0)}{2u_0[\alpha_S u_0^3 + A_Q\Sigma u_0^2 + Q_1 U(u_0)]}, \\ \text{c)}\ P_0 &= A_Q - 3u_0\Sigma . \end{aligned} \tag{244}$$

Solving the quadratic equation (243) we arrive at

$$R = \rho \pm \sqrt{\rho^2 - C_0}\,\sqrt{1 + D(\Phi - \Phi_0)} \tag{245}$$

with

$$\text{a) } C_0 = \frac{(Nu_0 - 2)u_0}{N\varkappa^2}, \quad \text{b) } D = \frac{2}{A_0 N\varkappa^2(\rho^2 - C_0)}, \quad \text{c) } \rho = \frac{Nu_0 - 1}{N\varkappa}. \tag{246}$$

This is the explicit form of the spiral equation received by approximation up to the second order in Φ.

By further power series expansion we get in first order (linearized form) the Archimedes spiral

$$\text{a) } R = r_0 \pm S_0(\Phi - \Phi_0) \quad \text{with} \quad \text{b) } S_0 = \tfrac{1}{2}D\sqrt{\rho^2 - C_0}. \tag{247}$$

Hence we find for the distance (at a fixed angle) between two spiral arms the formula

$$\Delta R = 2\pi|S_0|. \tag{248}$$

13. Numerical evaluation of the theory (model Milky Way)

Our next aim is to evaluate numerically for an orbiting test body the general formulas for its radial velocity and azimuthal velocity (rotation curve) as well as the formula for its spiral motion (superposition of the radial and azimuthal velocities).

The formulas presented above show that we need two different categories of parameters, namely first the "present" cosmological parameters as adiabatically fixed parameters determined by our cosmological model which we treated in our previous papers, and second the individual parameters which partly are rather well known by empirical observations. Partly we have to guess two parameters (dark matter parameter $\varkappa$, scalaric bremsheat parameter β_Q) in order to be in rough accordance with the observations from the motion of the orbiting stars (empirical rotation curves). Of course, our simplified model can only reflect some basic features of the astrophysics of galaxies. Specifically our further application of the above theory refers to a rough model of the Milky Way (Galaxy).

13.1. COSMOLOGICAL AND INDIVIDUAL PARAMETERS

Numerical cosmological values for the "present time": Here we use our cosmological results to derive from (51):

$$\begin{aligned} &\text{a) } \Sigma = 5.03 \cdot 10^{-19}\,\mathrm{s}, \quad \text{b) } \Sigma = -2.81 \cdot 10^{-36}\,\mathrm{s}^{-2}, \\ &\text{c) } \alpha_S = 1.05 \cdot 10^{-35}\,\mathrm{s}^{-2}. \end{aligned} \tag{249}$$

Numerical values for rough modelling of the Galaxy:

$$\begin{aligned} &\text{a)}\quad M_c &&= 1.8\cdot 10^{44}\,\mathrm{g} && \text{(central mass acting on the sun)}\,,\\ &\text{b)}\quad r_0 &&= 0.8\ \mathrm{kpc} && \text{(radius of the inner central body)}\,,\\ &\text{c)}\quad \varkappa &&= 0.04\ (\mathrm{kpc})^{-1} && \text{(dark matter fitting parameter)}\,. \end{aligned} \tag{250}$$

Numerical value of the scalaric bremsheat parameter (analog to sun matter, being explained later):

$$\beta_Q = 5.32\cdot 10^3\,. \tag{251}$$

Hence the parameter (227) and the quantity (231) take the form

$$\begin{aligned} &\text{a)}\quad \alpha_i &&= 7.16\cdot 10^{-30}\,\mathrm{s}^{-2},\\ &\text{b)}\quad \alpha_e &&= \left(1.05\cdot 10^{-5} + \tfrac{1.1\cdot 10^{-3}}{R}\ \mathrm{kpc}\right)\cdot 10^{-30}\,\mathrm{s}^{-2}\,. \end{aligned} \tag{252}$$

Concluding this subsection let us add some annotations to the scalaric bremsheat

Figure 7. Rotation curve (radial course of the azimuthal velocity) of stars about the center of a galaxy (model: sun)

Figure 8. Spiral motion of a cosmic object (star) ejected by the rotation of the central body of a galaxy

parameter. According to its definition (222) it mainly depends on following values of the inner central body of the Galaxy: quantity J (214c), cubic heat expansion coefficient α_c and heat capacity W (214b) which contains the specific heat c_Q of the central body. The heat consumption factor f_S seems to be of the order of magnitude 1. Let us further mention that we know the radius r_0 of the central body and roughly its angular velocity ω. Further we realize that the mass of the central body cancels. Therefore we are mainly left with the parameters α_c and c_Q . Let us for numerical estimates tentatively use the values for the sun, already applied above (158):

$$\text{a)}\quad \alpha_{\mathrm{csun}} \approx 3.66\cdot 10^{-3}\mathrm{K}^{-1}\,,\quad \text{b)}\quad c_{\mathrm{Qsun}} \approx 1.24\cdot 10^{8}\,\mathrm{cm}^2\,\mathrm{s}^{-2}\,\mathrm{K}^{-1}\,. \tag{253}$$

Hence we obtain for the sun the value $\beta_Q(251)$.

Fig. 7 shows the radial course of the azimuthal velocity V_Φ (abscissa R in kpc, ordinate V_Φ in km s^{-1}). This is the "rotation curve" following from our theory.

Plotting of the spiral of the orbiting body is based on the formula (245) exhibiting the parameters ρ, C_0 and D, which after some substitutions are determined by the equations (246). A rather lengthy numerical calculation leads to the values

$$\text{a)} \quad \rho = 1.3 \text{ kpc}, \quad \text{b) } C_0 = 1.5 \text{ (kpc)}^2, \quad \text{c) } D = -0.29 \,. \tag{254}$$

Fig. 8 shows the spiral, where the radial distance is given in kpc.

I would like to express my thanks to the E. Majorana Center Erice for hospitality as well as to the professors Venzo de Sabbata and A. Gorbatsievich (University of Minsk) for scientific discussions and help.

THE GEOMETRY OF MATTER FIELDS

Claus Lämmerzahl

Fakultät für Physik der Universität Konstanz

D-7750 Konstanz, Fed. Rep. Germany

Abstract: At first we derive a field equation by means of essentially geometry-free demands, that is, by means of a Cauchy-problem, superposition principle, finite propagation speed and a conservation law. These requirements characterise a symmetric hyperbolic system of partial differential equations of first order.

In what follows, the field equation will define the geometry of space-time (in the same way as light rays and point particles define 'their' geometry, cf. Ehlers, Pirani and Schild (1972)). A general discussion of the derived field equation leads to a metrical structure of Finslerian type, to the propagation of helicity states, to a path structure and to the propagation of spin states. We thereby investigate the concept of a generalised Clifford-algebra.

Specialisation to two light cones, two helicity and spin states and the requirement that there is at least one time-like group velocity, then leads to the usual Dirac equation which defines as its geometry a Riemann-Cartan space-time with axial torsion only and interaction with the Maxwell field.

1. Introduction

1.1. Description of the problem

The purpose of what follows is to show that on physical grounds at least in the classical region space-time geometry when defined by means of matter fields turns out to be a Riemann-Cartan geometry with axial torsion. Moreover, the Maxwell field seems to be the only additional field which can interact with the classical limit of these matter fields.

Usually space-time geometry is characterised by the motion of point particles. By means of physically reasonable assumptions this motion is described by a geodesic equation in a Weylian structure as was shown in the constructive axiomatics of Ehlers, Pirani and Schild (1972) (see also Castagnino (1971)). The point particles are thereby *test particles* which react on but do not influence geometry.

However, we know that all physical matter must be described quantum mechanically. Quantum mechanics is the theory of matter superior to classical mechanics. Therefore the above classically defined point particles must be replaced by quantum mechanical objects. And one way of describing them is by means of fields obeying some field equation.

Quantum Mechanics in Curved Space-Time
Edited by J. Audretsch and V. de Sabbata
Plenum Press, New York, 1990

The present approach to the determination of space-time geometry therefore makes use of matter fields as physical objects which 'feel' the geometry. That is, matter fields play the role of a *test field*. (For the measurement of fields compare the lectures of W. Unruh in this volume.) It is clear that the notion of geometry will thereby change. On the level of the field equations there will be neither any metric nor any connection; some generalised metric and connection will be introduced in discussing the propagation of the singularities of these fields and our usual Riemannian metric and linear connection will enter the consideration at a late stage only.

The program of our approach may be subdivided into three steps:

(i) First of all it is necessary to determine the dynamics of the test fields by means of *basic experiences* which will be formulated by means of *geometry-free axioms*, i.e. exclusively by means of differential topological demands on the test fields. In our case this dynamics results in the evolution equation for fields, respectively in the field equation.

(ii) The second step consists in an exploration of the geometry of the field equation involving a formulation of the geometry in physical terms. In this context 'physical terms' mean the development of field theoretical terms of geometry, for example, field theoretical analogues of metric, connection, curvature * and so on. Up to now there seem to be just two possible terms of geometry: first, as a characterisation of distinguished objects z_0 by a relation $A(z_0) = 0$, where the function A will be regarded as geometry. Secondly, as a (possibly universal) transportation law of some physical object z (with $z^{(k)}$ the kth derivative with respect to some parameter): $z^{(k)} = B(x, z, z', z'', \ldots, z^{(k-1)})$, where now the function B will be considered as geometry. The special cases of the conformal and projective structures are obvious. In this sense field equations can be discussed with respect to the characterisation and propagation of singularities and of the WKB-limit The sharpness of wave fronts may be of interest, too.

(iii) Demanding special properties from the matter fields of course specialises these fields. So one may try to characterise the Dirac-, the Schrödinger- or the Petiau-Duffin-Kemmer-equation. And the restriction to some special field equation also restricts the possible geometry which can be defined by means of these matter fields.

The aim of these steps is to obtain a description of the geometry of fields. According to the remarks in (ii) two kinds of geometry thereby arise: the geometry of the tangent space, that is the *kinematical geometry* (e.g. the Minkowski space as tangent space of a space with (pseudo-)Riemannian metric) and the geometry of the space-time manifold, that is the geometry of dynamical evolution, the *dynamical geometry* (e.g. a Riemann-Cartan geometry). Since the dynamics of the fields has been postulated in (i) this procedure provides us with a *dynamical definition* of both kinds of geometry.

Within this approach to field equations possible "reasonable" generalisations of the Dirac equation may also arise. In addition, hints towards or justification for the minimal coupling procedure in field equations can possibly be given. A better understanding of the usual Dirac equation in curved space-time may also be achieved firstly by recognising which ideas related to this equation will also survive in these more general cases and secondly by uniquely characterising the usual Dirac equation.

To emphasise, no coupling of any given field equation (for example a special relativistic one, for which already a special kinematical geometry has to be assumed) to some prescribed geometry will be carried out. But precisely the *fields and their dynamics will determine the geometry of space-time*. What we want is to proceed by way of analysis to geometry.

We emphasise in addition that all geometric fields, e.g. metric, torsion etc., will be considered as external fields; geometric fields are *not dynamical*.

There is a rather small body of literature dealing with this and related problems. To begin with, the following remark made by Ehlers (1973) may be regarded as the

* For example, for point particles curvature appears in describing geodesic deviation. Is there a notion of curvature in field theory?

initial motivation for dealing with field theory in connection with space-time axiomatics: "It is quite possible that such an analysis (maybe in terms of possible wave equations for massive particles) would show that a 'reasonable' description of matter only if the Weyl space is, in fact, Riemannian, ..." . Then Audretsch (1983) (followed by Audretsch *et al.* (1984), Loinger (1985) and Kasper (1986)) was the first to apply field theoretical concepts in this context by showing that the classical limit of the Dirac equation in a Weyl-space, which EPS arrived at, reduces that space indeed to a Riemann-space. Subsequently Liebscher (1985) derived the metric of space-time from a 4-component generalised Dirac equation alone. Together with Bleyer he discussed this approach in more detail in the following series of papers: Bleyer and Liebscher (1986) and (1987) and Bleyer (1988). The dynamical generation perspective of geometry has already been spelled out by Andersson (1987). In the present work even the dynamics of the fields will be given a foundation and, on this basis, such ideas will be consequently pursued to include the determination of some affine structures.

1.2. Description of the Work

The present work attempts to determine the space-time geometry according to the scheme described above.

First we assume that the space-time is a four-dimensional differentiable manifold which admits a (3+1)-slicing. Then the time evolution of a field, i.e. the possibility of preparing a field, will lead to an abstract Cauchy-problem. In combination with other first principles like a superposition principle, finite velocity of propagation and a conservation law, we get as an equation of motion for the test fields a wave equation which is a symmetric hyperbolic linear homogeneous system of partial differential equations of first order.

The geometrical content of this equation is given by the characteristics and the propagation of singularities of this system and leads to a conformal Finslerian structure of space-time. In addition we obtain the propagation of the helicity states which can test more than the Finslerian part of space-time structure, for example torsion. By

introducing a classical limit we get a path structure and also the propagation of spin states. The way of calculating the propagation of the singularities and the spin states, especially the notion of a generalised Clifford-algebra, seems to be new in literature.

In the end the special case of the Dirac-equation is characterised by means of the number of light cones and mass shells and their respective number of inner degrees of freedom. In this case we can derive the usual Clifford algebra and get as structure of space-time a Riemann-Cartan geometry with axial torsion together with an electromagnetic field with which the classical particles interact via charge and anomalous magnetic moment, as it is determined by the classical particle paths and the spin motion. The characterisation of the Dirac equation and the derivation of its geometrical content may be regarded as the main result of this work.

This result may be compared with the constructive axiomatics of Ehlers, Pirani and Schild (1972) who use the concepts of light rays and freely falling point particles to arrive at a Weylian structure with projective parameters and torsion of space-time remaining unspecified. Also only a conformal class of metrics can be defined. When the concept of a spin-vector according to Audretsch and Lämmerzahl (1988) is added to the light rays and point particles, torsion may be introduced to arrive at a Weyl-Cartan structure.

2. The field equation

To begin with, we want to set up the field equation on the basis of a number of experimentally motivated first principles. The geometrical contents of this field equation will be determined later in chapters 3 and 4. To this end a 4-dimensional differentiable manifold $\mathcal{M}$ will be assumed. Every point of this manifold is realised by an apparatus measuring quantities from which we assume the considered field φ can be calculated; thereby the fields φ are vector valued complex functions: $\varphi : \mathcal{M} \to \mathbf{C}^m : x \mapsto \varphi(x)$.

In order to set up the field equation we start with the most fundamental principle of physics, that is, the possibility of determining some measurable quantities out of a set of given quantities. The determined quantities are assumed to depend linearly on the given one. Next, finite propagation velocity and a conservation law restrict the determination equation to a first order symmetric hyperbolic system of partial differential equations.

In other words, in this chapter our strategy will be the following: We regard the given fields as solutions of some physical equation of motion (in fact, they *are* solutions because nothing else can be observed). Then from these solutions the feature of certain properties, which give information about its equation of motion, are axiomatically demanded . This is just the other way round than is usually found in mathematics where assumptions are made about the differential operator (e.g. Lipshitz-conditions) and information (existence, uniqueness) is derived about possible solutions.

2.1. The dynamical system

The dynamics of a field should have an evolutional structure: there should be at least one class of 3-dimensional non-intersecting hypersurfaces Σ_t consisting of measuring apparatus filling up all 'space' at a 'time' t. The Σ_t are parametrised by t, and all Σ_t are diffeomorphic to one another *. With reference to this parameter the evolution of the field, i.e. the progression of the field from Σ_t to $\Sigma_{t+\delta t}$ and so on, takes place. Before stating the corresponding axiom in ch. 2.2, we first want to express the above description by means of a mathematical definition (cf. Fisher and Marsden (1979)) and describe some related notions:

* The diffeomorphicity of all hypersurfaces Σ_t means that there will be no change in their topology. Such pecularities must be considered seperately. But as we are interested in local aspects of the space-time geometry only, we limit ourselves to an interval $[T_0, T]$ of the parameter range where no change in topology will occur.

Definition: *A $(3+1)$-slicing is a 3-dimensional differentiable manifold Σ and a class of embeddings $e_t : \Sigma \to \mathcal{M}$, $t \in \mathrm{I} = [T_0, T] \subset \mathbf{R}$, so that $e : \mathrm{I} \times \Sigma \to \mathcal{M} : (t, \mathrm{x}) \mapsto x = e(t, \mathrm{x}) = e_t(\mathrm{x})$ is a C^∞ -diffeomorphism.*

Therefore we can define

$$\Sigma_t := \{x \in \mathcal{M} \mid x = e_t(\mathrm{x}), \mathrm{x} \in \Sigma\}$$
$$\varphi_t := \varphi\,|_{\Sigma_t} : \Sigma_t \to \mathbf{C}^m$$
$$\widehat{\varphi}_t := e_t^*(\varphi) : \Sigma \to \mathbf{C}^m : \mathrm{x} \mapsto \widehat{\varphi}_t(\mathrm{x}) = \varphi(e_t(\mathrm{x})). \tag{2.1}$$

To put it the other way around: there should be a mapping e_t so that $\widehat{\varphi}_t$ via $\varphi(e_t(\mathrm{x}))$ fits to a field φ possessing no additional non-smoothness arising from e_t. That is, if $\widehat{\varphi}_t$ is a $\mathrm{C}^\infty(\Sigma)$-function then φ_t should be $\mathrm{C}^\infty(\Sigma_t)$ too. We can think of $\widehat{\varphi}_t$ as the field φ, as being measured by apparatus moving along the lines $v_\Sigma := \dfrac{de_t(\mathrm{x})}{dt}$.

The $\mathrm{C}^\infty(\Sigma)$-functions form a locally convex vector space, i.e. a Fréchet-space (Dieudonné (1971)). In addition, since Σ is a differentiable manifold, there is a partition of unitiy inducing a definite Riemannian metric $g^{(\Sigma)}$ on Σ so that integration can be performed. However, this metric is by no means physically characterised. Physical metrics will be encountered in ch. 3.

Now we want to demand that the fields obey an evolutional structure with respect to the slicing e_t. This means that if a field φ_{t_0} is prepared on Σ_{t_0} then the field φ_t on Σ_t for $t \geq t_0$ will be uniquely determinable. This usually is called Hadamard's *principle of scientific determinism* (cf. Hille and Phillips (1957)) *. Thereby it should be possible to pose arbitrary initial data φ_{t_0}. Especially all $\mathrm{C}^\infty(\Sigma_t)$-functions could be posed. **

Mathematically the initial dates play the role of labels of the set of solutions. If the manifold $\mathcal{M}$ possesses some symmetries, e.g. a 'time'-like Killing vector, then the respective conserved quantities can serve as labels as well. While the latter labels are appropriate in connection with quantum mechanics (these labels are measurable) the former are of no physical importance in quantum mechanics. However, in the case of symmetries, one label can be transformed to the other one, therefore being mathematically equivalent. Therefore, also in the context of a realisation of quantum mechanics by means of classical field theory there exists labels in the form of initial dates although they are not measurable. In the following, the existence of this kind of label will be assumed.

With respect to the slicing e_t this means that posing an arbitrary $\widehat{\varphi}_{t_0} =: \widehat{\varphi}_0 \in \mathrm{C}^\infty(\Sigma)$ will uniquely determine the $\widehat{\varphi}_t$ for $t \geq t_0$. We fix the regularity of $\widehat{\varphi}_t$ by demanding to be in $\mathrm{C}^\infty(\Sigma)$ too; in addition the determined $\widehat{\varphi}_t$ should be twice differentiable with respect to t:

Axiom 1: (Evolution)
(i) *$\exists (3+1)$-slicing so that $\forall t, t_0 \in \mathrm{I} \subset \mathbf{R}, t \geq t_0$ posing $\widehat{\varphi}_{t_0} \in \mathrm{C}^\infty(\Sigma)$ uniquely determines $\widehat{\varphi}_t \in \mathrm{C}^\infty(\Sigma)$.*
(ii) *The mapping $\mathrm{I} \to \mathrm{C}^\infty(\Sigma) : t \mapsto \widehat{\varphi}_t$ whereby $\widehat{\varphi}_t$ is determined according to* (i) *is in $\mathrm{C}^2(\mathrm{I}, \mathrm{C}^\infty(\Sigma))$.* ***

---

* We do not consider equations of motion with constraints.

** Indeed, more general functions, e.g. distributions, may be taken. However, since we want to derive necessary conditions on the evolution only, limitation to smaller function spaces is appropriate. Beside this, it may seem to be necessary to limit ourself on functions or distributions with compact support because only such functions can be experimentally prepared. However, if solutions propagate with infinite velocity then $\mathrm{supp}\varphi_t$ which then acts as initial data for $\varphi_{t'}$ with $t' \geq t$ may not be compact; therefore it is necessary to choose as initial dates functions with noncompact support.

*** A mapping $t \mapsto \widehat{\varphi}_t$ is called *differentiable* if there exists a $\chi \in \mathrm{C}^\infty(\Sigma)$ so that

$$\lim_{h \to 0} p_{K,j}\left(\frac{1}{h}(\widehat{\varphi}_{t+h} - \widehat{\varphi}_t) - \chi\right) = 0$$

The first part of the axiom implies that there is a mapping

$$U : \mathbf{I} \times \mathbf{I} \times \mathrm{C}^\infty(\Sigma) \to \mathrm{C}^\infty(\Sigma) : (t, t_0, \widehat{\varphi}_{t_0}) \mapsto \widehat{\varphi}_t = U(t, t_0, \widehat{\varphi}_0) \tag{2.2}$$

in the triangle $t \geq t_0$. Since $\widehat{\varphi}_t$ again acts as an initial date we get the composition law

$$U(t', t, U(t, t_0, \widehat{\varphi}_0)) = U(t', t_0, \widehat{\varphi}_0) \qquad \forall t' \geq t \geq t_0. \tag{2.3}$$

Of course

$$U(t, t, \widehat{\varphi}_t) = \widehat{\varphi}_t \qquad \forall t \in \mathbf{I}. \tag{2.4}$$

The second part of the axiom implies

$$\lim_{s \to t'} U(s, t, \widehat{\varphi}_t) = U(t', t, \widehat{\varphi}_t). \tag{2.5}$$

The properties (2.2-5) define U to be a ***dynamical system***.

2.2. The superposition principle

All interference experiments with quantum matter show that it obeys the superposition principle, see for example Rauch (1983). We will formalise this experience in demanding the linearity of the determination of $\varphi_{t'}$ from the functions φ_t. With respect to the slicing e_t we therefore demand:

Axiom 2: (Superposition).
$\forall \widehat{\varphi}_t, \widehat{\psi}_t \in \mathrm{C}^\infty(\Sigma), \forall \alpha, \beta \in \mathbf{C} : \widehat{\varphi}_{t'} = U(t', t, \widehat{\varphi}_t) \wedge \widehat{\psi}_{t'} = U(t', t, \widehat{\psi}_t) \Rightarrow \alpha\widehat{\varphi}_{t'} + \beta\widehat{\psi}_{t'} = U(t', t, \alpha\widehat{\varphi}_t + \beta\widehat{\psi}_t)$.

Therefore U will be linear: $U(t', t, \widehat{\varphi}_t) =: U(t', t)\widehat{\varphi}_t$ and (2.3.) changes to

$$U(t'', t')U(t', t) = U(t'', t).$$

The set of all U constitutes a ***semigroup*** and each U is called ***propagator*** or ***evolution operator*** in the locally convex vector spaces $\mathcal{E}(\Sigma)$.

2.3. The abstract Cauchy-problem

For the above semigroup we can define the ***infinitesimal generator*** $\widehat{G}_t$ which depends on t (e.g. Komura (1968), Yoshida (1971)): from the definition of the derivative of $\widehat{\varphi}_t$ which evolved from a prepared $\widehat{\varphi}_0$ we have in $\mathcal{E}$

$$\begin{aligned} \frac{d\widehat{\varphi}_t}{dt} &= \lim_{h \to 0+} \frac{1}{h}(\widehat{\varphi}_{t+h} - \widehat{\varphi}_t) \\ &= \lim_{h \to 0+} \frac{1}{h}(U(t+h, t_0) - U(t, t_0))\widehat{\varphi}_{t_0} \\ &= \lim_{h \to 0} \frac{1}{h}(U(t+h, t) - \mathrm{Id})\widehat{\varphi}_t \\ &=: \widehat{G}_t \widehat{\varphi}_t \end{aligned} \tag{2.6}$$

with the domain of $\widehat{G}_t$, $D(\widehat{G}_t) \subset \mathrm{C}^\infty(\Sigma)$ consisting of those $\widehat{\varphi}_t$ for which this limit exists. With this definition we get the ***abstract Cauchy-problem*** or the ***evolution equation***

$$\frac{d\widehat{\varphi}_t}{dt} = G_t \widehat{\varphi}_t \qquad \text{with} \qquad \widehat{\varphi}_{t_0} = \widehat{\varphi}_0. \tag{2.7}$$

---

where $p_{K,j}$ is the set of semi-norms in $\mathcal{E}(\Sigma)$. The function χ is then called $\frac{d}{dt}\widehat{\varphi}_t$.

of which $U(t,t_0)\varphi_0$ is a solution. According to axiom 1(ii) $D(\widehat{G}_t)$ is nonempty for all $t \geq T_0$ and indeed equals $\mathcal{E}(\Sigma)$.

If $\widehat{G}_t = \widehat{G}$ does not depend on time, then the assumption of strong continuity of the mapping $t \to \widehat{\varphi}_t$ is enough to show that the abstract Cauchy-problem is well posed (Yosida (1971), Komura (1968)). However, for our general case there seems to be no corresponding theorem so that we need a much stronger assumption.

2.4. Finite propagation speed

It is a fundamental experience in physics that all phenomena do not propagate instantaneously but always need a finite time to reach a separated point. To formalise this experience we first define the speed of propagation.

Let $\widehat{\varphi}_{n,t}$ be a sequence in $C^\infty(\Sigma)$ with $\mathrm{supp}\widehat{\varphi}_{n,t} \to \{x\}$ for $n \to \infty$ then the x- and t-dependent propagation speed may be defined as

$$c(x,t) := \lim_{t'\to t} \lim_{n\to\infty} \sup\left\{ \frac{\sigma(x',x)}{t'-t} \;\middle|\; x' \in \mathrm{supp}\widehat{\varphi}_{n,t'} \right\}.$$

$\sigma(x',x)$ is the geodesic length within Σ between x and x' and $\widehat{\varphi}_{n,t'} = U(t',t)\widehat{\varphi}_{n,t}$. The definition is independent of the chosen sequence. * For some bounded region $\Omega \subset \Sigma$ and for some finite time-interval I we can define the maximum speed $c(\Omega, I) := \sup\{c(x,t) \mid x \in \Omega, t \in I\}$.

The basic experience is described by our

Axiom 3: *All fields propagate with finite velocity.*

First this means that compact $\mathrm{supp}\varphi_t$ implies compact $\mathrm{supp}\varphi_{t'}$. Since an embedding maps compact sets into relatively compact sets we get with respect to the slicing e_t

$$U(t',t) : C_0^\infty(\Sigma) \to C_0^\infty(\Sigma).$$

Following an idea of Svendsen (1982) we can show

Theorem: *$\widehat{G}_t$ is a differential operator.*

Proof. We show first that $x \notin \mathrm{supp}\widehat{\varphi}_t \Rightarrow x \notin \mathrm{supp}\left(\widehat{G}_t\widehat{\varphi}_t\right)$. If $x \notin \mathrm{supp}\widehat{\varphi}_t$ then $\exists U \subset \Sigma, U$ compact, with $\mathrm{supp}\widehat{\varphi}_t \subset U, \mathrm{supp}\widehat{\varphi}_t \neq U$ and $x \notin U$. Since $\widehat{\varphi}_t$ propagates with finite velocity there is a $\delta t > 0$ so that $\mathrm{supp}\widehat{\varphi}_{t+\delta t} \subset U$. Then $x \notin \mathrm{supp}\widehat{\varphi}_{t+\delta t}$ and therefore $x \notin \mathrm{supp}\frac{1}{\delta t}(\widehat{\varphi}_{t+\delta t} - \widehat{\varphi}_t)$ which implies by definition (2.6) that $x \notin \mathrm{supp}\left(\widehat{G}_t\widehat{\varphi}_t\right)$.

Therefore $\widehat{G}_t$ does not increase support, i.e. $\widehat{G}_t$ is a local operator. In addition, $\widehat{G}_t$ is a linear operator with $D(\widehat{G}_t) = C_0^\infty(\Sigma)$. According to Dieudonné (1971) then it must be a differential operator of finite order with coefficients which are $C^\infty(\Sigma)$-functions.■ **

For the evolution eqtn. we then get (in the multi-index notation; tensors on Σ are written with latin indices ranging from 1 to 3)

$$\frac{d\widehat{\varphi}_t}{dt} = \sum_{|\alpha|=0}^{N} {}^{|\alpha|}\widetilde{G}_t^{(\alpha)}\widehat{\partial}_{(\alpha)}\widehat{\varphi}_t \tag{2.8}$$

---

* According to (2.5) $U(t',t)\widehat{\varphi}_t \to \widehat{\varphi}_t$ for $t' \to t$. Therefore we can conclude that $\mathrm{supp}\widehat{\varphi}_t = \mathrm{supp}\widehat{\psi}_t \Rightarrow \mathrm{supp}\big(U(t',t)\widehat{\varphi}_t\big) = \mathrm{supp}\big(U(t',t)\widehat{\psi}_t\big)$ for $t' \to t$.

** Since the cited theorem is true only if the premises concerning the domain of $\widehat{G}_t$ hold, we had to make the strong assumption of axiom 1(ii).

where ${}^{|a|}\widehat{G}_t^{(a)}$ are functions of x and $\widehat{\partial}$ acts on x only. Therefore finite velocity forces $\widehat{G}_t$ to be a *local operator* and the evolution eqtn. to be a system of partial differential equations.

2.5. A conservation law

Next we want to explore the basic experience that during evolution no matter will be created nor annihilated ($d^3\Sigma$ is the invariant volume element $\sqrt{g^{(\Sigma)}}d^3\mathrm{x}$):

Axiom 4: *For all solutions of* (2.8): $\int_\Sigma \widehat{\varphi}_t^+ \widehat{\varphi}_t d^3\Sigma = const.$

For the propagator U this means that

$$\int_\Sigma (U(t',t)\widehat{\varphi}_t)^+ U(t',t)\widehat{\varphi}_t d^3\Sigma = const. \tag{2.9}$$

From this eqtn. we shall deduce that $\widehat{G}_t$ is of order one only * and has Hermitian coefficients (Svendson (1984)).

At first, from differentiating (2.9) and using (2.7) we see that $\widehat{G}_t$ is formally skew-adjoint, that is $\int_\Sigma((\widehat{G}_t\varphi)^+\varphi + \varphi^+\widehat{G}_t\varphi)d^3\Sigma = 0 \quad \forall\varphi \in C_0^\infty(\Sigma)$ which implies

$$(\widehat{G}_t\widehat{\varphi}_t)^+\widehat{\varphi}_t + \widehat{\varphi}_t^+\widehat{G}_t\widehat{\varphi}_t = \widehat{\partial}_b\left(\mathrm{Re}\sum_{|a|=0}^{N-1}\widehat{\varphi}_t^+ A^{b(a)}\widehat{\partial}_{(a)}\widehat{\varphi}_t\right) \tag{2.10}$$

for some coefficients $A^{b(a)}$. On the right hand side inside the bracket the order of the derivative is one less than in $\widehat{G}_t$. Especially the highest order coefficients obey $\left({}^N\widehat{G}_t\right)^+ = (-1)^N\left({}^N\widehat{G}_t\right)$. The skew-adjointness of $\widehat{G}_t$ implies the time-independence of $\int_\Sigma \widehat{\varphi}_t^+\widehat{\psi}_t d^3\Sigma$ and the reality of $\int_\Sigma \widehat{\varphi}_t^+\left(i\frac{d}{dt}\widehat{\varphi}_t\right)d^3\Sigma$ for all $\widehat{\varphi}_t, \widehat{\psi}_t \in C_0^\infty(\Sigma)$.

For an appropriate small neighbourhood $U(\mathrm{x}_0)$ we define closed balls $B(\mathrm{x}_0, R) \subset U(\mathrm{x}_0) \subset \Sigma$ with center x_0 and geodesic radius R. With these notions and ($c := c(U(\mathrm{x}_0), \mathrm{I})$)

$$I(t',t) := \int_{B(\mathrm{x}_0, r+c|t'-t|)} (U(t',t)\widehat{\varphi}_t)^+ U(t',t)\widehat{\varphi}_t d^3\Sigma$$

it is easy to prove (Svendsen (1982))

Lemma: $\quad I(t',t) \geq I(t,t).$

Interpreting $\widehat{\varphi}_t^+\widehat{\varphi}_t$ as probability density this lemma means that no probability can leave the truncated cone (with supp$\widehat{\varphi}_t$ as one base and supp$\widehat{\varphi}_{t'}$ as the other) through its mantle.

This lemma shows that

$$\lim_{t'\to t+}\frac{dI(t',t)}{dt'} \geq 0.$$

---

* Hörmander (1984), §23, proved that if for a *scalar* partial differential eqtn. the Cauchy problem is valid and solutions propagate with finite velocity only, then the hypersurface Σ_t cannot be characteristic. If this theorem is true for systems also, finite velocity is enough to reduce the order of $\widehat{G}_t$ to one. However, up to now a proof is lacking.

Using the definition of $I(t',t)$ and $\widehat{G}_t$ we get

$$-\int_{B(\mathbf{x}_0,r)} \left((\widehat{G}_t\widehat{\varphi}_t)^+\widehat{\varphi}_t + \widehat{\varphi}_t^+\widehat{G}_t\widehat{\varphi}_t \right) d^3\Sigma \quad \leq \quad c \int_{\partial B(\mathbf{x}_0,r)} \widehat{\varphi}_t^+\widehat{\varphi}_t d^2\Sigma. \tag{2.11}$$

This is a necessary condition which the differential operator has to fulfill.

For later purpose we show that the abstract time-derivative can be transcribed to a derivative within $\mathcal{M}$. For $\widehat{\varphi}_t \in C^\infty(\Sigma)$ we also have $\frac{d}{dt}\widehat{\varphi}_t \in C^\infty(\Sigma)$ and show

Lemma: $\left(\frac{d\widehat{\varphi}_t}{dt}\right)(\mathbf{x}) = \frac{d}{dt}(\widehat{\varphi}_t(\mathbf{x}))$.

Proof: Defining $\widehat{\varphi}(t,\mathbf{x}) := \widehat{\varphi}_t(\mathbf{x})$ we have $\left(\frac{d}{dt}\widehat{\varphi}_t\right)(\mathbf{x}) = \frac{\partial}{\partial t}(\widehat{\varphi}(t,\mathbf{x}))$ since

$$\lim_{h\to 0} p_{K,j}\left(\frac{1}{h}(\widehat{\varphi}(t+h,\mathbf{x}) - \widehat{\varphi}(t,\mathbf{x})) - (\frac{d\widehat{\varphi}_t}{dt})(\mathbf{x})\right) = 0$$

for all $j = 1,2,\ldots$ ($p_{K,j}$ is the set of seminorms in $\mathcal{E}(\Sigma)$). Regarding $\mathbf{x}$ in $\frac{\partial}{\partial t}\widehat{\varphi}(t,\mathbf{x})$ as parameter we can write $\frac{\partial}{\partial t}\widehat{\varphi}(t,\mathbf{x}) = \frac{d}{dt}(\widehat{\varphi}(t,\mathbf{x})) = \frac{d}{dt}(\widehat{\varphi}_t(\mathbf{x}))$ ■

Therefore this lemma especially means that $\widehat{\varphi}_t \in C^1(\mathbf{I}, C_0^\infty(\Sigma))$ implies $\widehat{\varphi} \in C^1(\mathbf{I}\times\Sigma)$. Since in addition according to axiom 1(ii) $\widehat{\varphi}_t \in C^2(\mathbf{I}, C_0^\infty(\Sigma))$ we have $\widehat{\varphi} \in C^2(\mathbf{I}\times\Sigma)$, so that $\varphi \in C^2(\mathcal{M})$.

Now one can show (slightly generalising Svendsen (1982))

Theorem: *The evolution eqtn. is a first order symmetric hyperbolic system of partial differential eqtns. on $\mathcal{M}$*

Proof: Using Stoke's theorem we get from the inequality (2.11) and eqtn. (2.10)

$$-\int_{\partial B(\mathbf{x}_0,r)} 2\mathrm{Re}\sum_{|\alpha|=0}^{N-1} \widehat{\varphi}_t^+ A^{b(\alpha)}\widehat{\partial}_{(\alpha)}\widehat{\varphi}_t n_b d^2\Sigma \quad \leq \quad c\int_{\partial B(\mathbf{x}_0,r)} \widehat{\varphi}_t^+\widehat{\varphi}_t d^2\Sigma, \quad \forall\widehat{\varphi}_t \in C_0^\infty(\Sigma)$$

where n with $g^{(\Sigma)}(n,n) = -1$ is the normal to $\partial B(\mathbf{x}_0,r)$. For $N > 1$ on the left hand side there appear derivations while on the right hand side there are no. Therefore we can construct a function $\widehat{\varphi}_t$ contradicting this inequality so that necessarily $N \leq 1$, that is $\widehat{G}_t = {}^1\widehat{G}_t^a\widehat{\partial}_a + {}^0\widehat{G}_t$ reducing (2.7) to a first order system:

$$\frac{d}{dt}\widehat{\varphi}_t = {}^1\widehat{G}_t^a\widehat{\partial}_a\widehat{\varphi}_t + {}^0\widehat{G}_t\widehat{\varphi}_t. \tag{2.12}$$

From (2.10) we conclude that $\widehat{G}_t^a$ is Hermitian, so that we arrive at a first order symmetric hyperbolic system.

This equation can be written on the manifold $\mathcal{M}$: with the help of the above lemma we have

$$\left(\frac{d\widehat{\varphi}_t}{dt}\right)(\mathbf{x}) = \frac{d}{dt}(\widehat{\varphi}_t(\mathbf{x})) = \frac{d}{dt}((e_t^*(\varphi))(\mathbf{x})) = \frac{d}{dt}(\varphi(e_t(\mathbf{x}))) = (v_\Sigma(\varphi))(x) = (\partial_0\varphi)(x)$$

at $x = e_t(\mathbf{x})$ in a chart with $v_\Sigma^\mu = \delta_0^\mu$. With this result and the definitions $de_t({}^1\widehat{G}_t) =: {}^1G \in T\Sigma_t \subset T\mathcal{M}, e_t({}^0\widehat{G}_t) =: {}^0G$ (both coefficients are $C^1(\mathcal{M})$) we arrive at $\partial_0\varphi = {}^1G^{\hat{\mu}}\partial_{\hat{\mu}}\varphi + {}^0G\varphi$ (vectors lying within Σ_t are written with hatted indices) which after

multiplication with an arbitrary matrix $i\tilde{\gamma}^0$ with $\det\tilde{\gamma}^0 \neq 0$ can be rewritten as ($\tilde{\gamma}^{\hat{\mu}} := -\tilde{\gamma}^0\left({}^1G^{\hat{\mu}}\right), M := -i\tilde{\gamma}^0\left({}^0G\right)$)

$$0 = i\tilde{\gamma}^\mu \partial_\mu \varphi - M\varphi \tag{2.13}$$

$$\exists A, \det A \neq 0: \quad (A\tilde{\gamma}^\mu)^+ = A\tilde{\gamma}^\mu. \tag{2.14}$$

The fact that $\varphi \in C^2(\mathcal{M})$ especially implies that also the coefficients $\tilde{\gamma}^\mu, M \in C^1(\mathcal{M})$.

In order that (2.13) is a hyperbolic system we have to show that the polynomial $H(x,k) := \det(\tilde{\gamma}^\mu k_\mu)$ is hyperbolic. This is easy to see: Since $H(x,k) = 0 \Leftrightarrow \det({}^1G^{\hat{\mu}}k_{\hat{\mu}} - k_0) = 0$ with Hermitian ${}^1G^{\hat{\mu}}$ the eigenvalues k_0 are real, so that for given real $k_{\hat{\mu}}$ the equation $H(x,k) = 0$ has only real k_0 as solutions. In addition, $H(x, \partial\Sigma_t)$ cannot vanish: if it vanishes then the surface Σ_t is characteristic contradicting axiom 1(i) which states that one can pose arbitrary initial data on Σ_t (cf. Courant and Hilbert (1962)).

Therefore (2.13) is a symmetric hyperbolic system of first order. ■

(2.13) is the differential equation, the *generalised Dirac equation*, we looked for. (For a survey of partial differential equations and especially the notion of hyperbolicity see e.g. Gårding (1985)) The main principles we used to arrive at this equation are the Cauchy-Problem, superposition-principle, finite propagation speed and a conservation law.

It should be noted that according to our approach the matrices $\tilde{\gamma}^\mu$ and M are not uniquely fixed by the solutions φ but are free to be multiplied by a common arbitrary nonsingular matrix. Therefore only the equivalence class defined by $(\tilde{\gamma}^\mu, M) \sim (\tilde{\gamma}'^\mu, M') := (A\tilde{\gamma}^\mu, AM)$, A arbitrary, nonsingular, is physically meaningful. These requirements leave the Hermiticity condition invariant too.

The generalised Dirac equation above does *not* provide us with the notion of any connection (as for example the path of a particle does). However, demanding invariance under $Gl(m, \mathbf{C})$-transformations $\varphi \to \varphi' := S\varphi$ the coefficients in (2.12) have to transform according to $\tilde{\gamma}'^\mu = S\tilde{\gamma}^\mu S^{-1}, M' := SMS^{-1} - iS\tilde{\gamma}^\mu \partial_\mu S^{-1}$. Therefore M transforms rather similar to a connection.

We note that from axiom 4 a conservation law can be inferred: starting from (2.10) with $N = 1$ we get $\frac{d}{dt}(\widehat{\varphi}_t^+ \widehat{\varphi}_t) = \widehat{\partial}_{\hat{0}}(\widehat{\varphi}_t^{+\,1}\widehat{G}_t^{\hat{0}}\widehat{\varphi}_t)$. With the above lemma we get for the left hand side $\partial_0(\varphi^+\varphi)$ and similarly for the right hand side $\partial_{\hat{\mu}}(\varphi^{+\,1}G^{\hat{\mu}}\varphi)$, that is, with the above definitions

$$\partial_\mu(\varphi A\tilde{\gamma}^\mu \varphi) = 0. \tag{2.15}$$

Of course, for symmetric hyperbolic systems a uniqueness result holds (Courant and Hilbert (1962)) recovering the uniqueness of axiom 1.

Another observation is that with the above results it is possible to show that one can choose other slicings of the manifold $\mathcal{M}$ for which the axioms 1 to 4 are true.

3. The propagation of singularities: introduction of a metrical structure and propagation of helicity states

Singularities are discontinuities in the solutions of partial differential equations or in one of their derivatives. The occurence of singularities is one of their definite mathematical and physical features and so can be regarded as a physical phenomenon impressing some characteristic structure onto the differential manifold $\mathcal{M}$.

As one main result of this chapter these characteristics will define a conformal Finslerian stucture, endowing the manifold with a (quite general) metric.

Up to now, methods of Finslerian geometry found physical applications only in the domain of solid state physics describing the geometry of sound waves in acoustical anisotropic and inhomogeneous media (cf. Meyer and Schroeter (1981)). It is also be

conceivable that some possible optical anisotropic and inhomogeneous media effects (i) the splitting of the light cone inside this medium into two cones due to the interaction of the helicity of light with the electrons (compare Nicol's prism) and (ii) different speeds of light in different directions (see the letter of W. Barthel in Matsumoto (1970)). Other possibilities of physical realisations of Finsler geometry are purely speculative in the sense that there might be (beyond today's measuring possibilities) in nature a more general than a Riemannian measuring of lengths (cf. Riemann (1854), Reichenbach (1928) and the letter of Finsler in Matsumoto (1970)).

In our approach the possibility of a Finslerian structure is traced back to the discussion of some field equation, in this way providing some theoretical reasons for taking this concept into account. If we do not observe any Finslerian effects, then we have to reduce the field equation so as to lead to a Riemann space only.

Another main result of this chapter concerns the idea of a characteristic Clifford-algebra that forms part of a generalised Clifford-algebra, which will be derived in section 4.3. The main feature of such an algebraic structure consists in connecting the 'inner' space $\mathbf{C}^m$ represented by the γ-matrices and derived quantities, with the tangent space $T\mathcal{M}$.

There is a large amount of physical and mathematical examinations of the Clifford algebra connected with the usual Dirac equation. On the contrary, up to now generalised Clifford algebras are used in a very formal way only to describe the linearising of n-forms (Roby (1969)), which can be connected with the linearising of some special hypothetical n^{th}-order scalar wave equations (Nono (1971)). A short review of present concepts of generalised Clifford algebras has been given by Childs (1978). All these are purely mathematical considerations. A special case based on the Lorentz-group has been introduced on physical grounds by Duffin (1938) Kemmer (1939), Bhabba (1949) and Harish-Chandra (1947) (see also Wightman (1970)). The generalised Clifford-algebra obtained by us is even more general than those considered in the literature.

In our case this concept - which can be used to discuss systems of partial differential equations, especially to calculate the propagation of helicity states along the light rays - will be given more mathematical and physical motivation and meaning. In this work the calculation of the propagation of helicity states is done independently of the work of Dencker (1982) who takes a broader class of differential operators - pseudodifferential operators of real principal type - into account but limits himself to a Hamiltonian formulation of the equation of motion of the polarisation sets, the distribution formulation of helicity states.

Another result of this chapter is that all the notions used in connection with a Riemannian metric, e.g. measuring of length, invariant volume element, orthogonality, Lorentz-group, tetrads, an isomorphism between covariant and contravariant vectors etc., can also be transcribed to the Finslerian case without changing its principles; 'only' technical complications will come along with it.

3.1. The singularities

We assume that a jump, i.e. a singularity *, in the function φ or in its derivatives may occur at some surface $\Phi(x) = 0$, called jump-surface. For describing a function φ having jumps up to order N (that means up to the Nth derivative) let us begin with the ansatz

$$\varphi(x) = \sum_{i=0}^{N} \left(S^{(i)}(\Phi)\right)(x) a^{(i)}(x) + R(x)$$

with $a^{(i)}, R \in C^{\infty}(M)$ and $S^{(n)}(\Phi) := \frac{1}{n!}\eta(\Phi)\Phi^n$ (η is the Heaviside function). Since φ should be a (generalised) solution of the field equation we insert this series into (2.13) and perform the differentiation taking $\partial_\mu \left(S^{(n)}(\Phi)\right)(x) = (S^{(n-1)}(\Phi))(x)(\partial_\mu \Phi)(x)$

* Singularities of solutions of differential equations are here defined along the lines of Courant and Hilbert(1962). Mathematically more sound may be the notion of the wave front set (Hörmander (1984)) resp. of the polarisation set (Dencker (1984)).

($S^{(-1)}$ is the δ-function) into account:

$$0 = i\tilde{\gamma}^\mu(\partial_\mu\Phi)a^{(0)}S^{(-1)}(\Phi) + \sum_{i=0}^{N-1}\left[i\tilde{\gamma}^\mu(\partial_\mu\Phi)a^{(i+1)} + i\tilde{\gamma}^\mu\partial_\mu a^{(i)} - Ma^{(i)}\right]S^{(i)}(\Phi)$$
$$+\left(i\tilde{\gamma}^\mu\partial_\mu a^{(N)} - Ma^{(N)}\right)S^{(N)}(\Phi) + i\tilde{\gamma}^\mu\partial_\mu R - MR$$

All coefficients to the $S^{(i)}(\Phi)$ have to vanish independently so that the following series of equations relating the hypersurface Φ to the functions $a^{(i)}$ arise:

$$0 = i\tilde{\gamma}^\mu(\partial_\mu\Phi)a^{(0)} \tag{3.1}$$
$$0 = i\tilde{\gamma}^\mu(\partial_\mu\Phi)a^{(i+1)} + i\tilde{\gamma}^\mu\partial_\mu a^{(i)} - Ma^{(i)}, \quad i = 1, ..., N-1 \tag{3.2}$$
$$0 = (i\tilde{\gamma}^\mu\partial_\mu a^{(N)} - Ma^{(N)})S^{(N)}(\Phi) + i\tilde{\gamma}^\mu\partial_\mu R - MR$$

These $N+1$ equations describing the jumps $a^{(i)}$ along a hypersurface $\Phi = 0$ are now the basis for the remainder of this chapter. If the function φ has no jump of order 0 then it is clear that (3.1) is always valid for the jump of lowest order.

3.2. The geometry of the jump-surfaces

If the field possesses a jump, say of order j, then $a^{(j)}$ cannot be zero implying that the coefficients in (3.1) fulfill the characteristic equation as solvability condition (after multiplication with A from (2.14)) with $\tilde{\gamma}^\mu := A\tilde{\gamma}^\mu$:

$$0 = \det(\tilde{\gamma}^\mu\partial_\mu\Phi). \tag{3.3}$$

Because of (2.14) this is just one real equation relating the hypersurfaces $\Phi = 0$ to the coefficients $\tilde{\gamma}^\mu$. Defining the normal $k_\mu := -\partial_\mu\Phi$ (3.3) gives $0 = \det\left((\tilde{\gamma}^0)^{-1}\tilde{\gamma}^{\hat{\beta}}k_{\hat{\beta}} + k_0\right)$ which is a determination equation for the eigenvalues k_0 of $(\tilde{\gamma}^0)^{-1}\tilde{\gamma}^{\hat{\beta}}k_{\hat{\beta}}a = -k_0 a$. The set of eigenvectors a (we omit the index (j)) is complete and all k_0 are real. Introducing $H(x,k) := \det(\tilde{\gamma}^\mu k_{\mu'})$ (3.3) reads

$$0 = H(x,k) = \sum_{|\alpha|=m} g_m^{(\alpha)}k_{(\alpha)} =: g_m(k,\ldots,k)$$

defining a totally symmetric covariant tensorfield g_m of mth rank. g_m is determined by the $m \times m$-matrices γ^μ and is therefore $C^\infty(\mathcal{M})$.

In general $H(x,k)$ consists of a product of several irreducible polynomials:

$$H(x,k) = \prod_{r=1}^{R}\left(H^{(r)}(x,k)\right)^{\alpha_r} \quad \text{with} \quad \sum_{r=1}^{R} m_r\alpha_r = m. \tag{3.4}$$

m_r is the degree of $H^{(r)}$ and all the $H^{(r)}$ are irreducible. Each $H^{(r)}$ must possess m_r solutions because H possesses m of it (some of them may be equal). The multiplicity of the zeros of the characteristic equation becomes important for the determination of the jumps a (see ch. 3.4). For the rest of this chapter we will drop the index $^{(r)}$; all statements are with respect to one of the irreducible polynomials.

If we determine the coefficients γ^μ by measuring the field φ, then we also know the g_m only up to multiplication with a scalar leading to the conformal structure

$$[g_m]_c := \{g'_m \mid g'_m = e^{\lambda(x)}g_m, \lambda(x) \in \mathbf{R}\}. \tag{3.5}$$

g_m can also be determined by measuring the normals k_μ and using (3.4).

(3.4) represents a differential equation of Hamilton-Jacobi-type from which the possible jump-hypersurfaces may be determined. This equation always possesses a solution if $\frac{\partial}{\partial k_\mu} H(x,k)\big|_{H(x,k)=0} \neq 0$ for at least one $\mu = 0, \ldots, 3$ (Carathéodory (1956)). However, especially $\frac{\partial}{\partial k_0} H(x,k)$ cannot vanish since, as will be seen in ch. 3.4, $H(x,k) = 0$ can possess simple zeros only. Consequently, in our case $H(x,k) = 0$ always possesses a solution $\Phi(x)$.

Jump-surface can also be interpreted as characteristic surfaces (Courant and Hilbert (1962)).

The *normal cone* at $x \in \mathcal{M}$ is $N_x := \{k \in T_x^*\mathcal{M} \mid H(x,k) = 0\}$ and describes a conic algebraic surface in the cotangent space. N_x is a cone without isolated k's and there cannot exist two closed parts of two cones which neither intersect one another nor lay inside one another. Therefore there is an open cone $\Gamma(\gamma, \Sigma_t)$ consisting of all $q \in T_x^*\mathcal{M}$ so that for each $k \neq q$ the equation $H(x, k + \lambda q) = 0$ has m solutions. The *hyperbolicity cone* $\Gamma(\gamma, \Sigma_t)$ is convex and $\partial_\mu \Sigma_t \in \Gamma(\gamma^\mu, \Sigma_t)$.

For obtaining information about the smoothness of the normal cone we recall that $\frac{\partial}{\partial k_0} H(x,k)$ never vanishes. According to lemma A.1.1. of Hörmander (1984) solutions $k_0 = k_0(x, k_{\hat\mu})$ of $H(x,k) = 0$ are therefore locally analytical which implies that $\frac{\partial}{\partial k_{\hat\mu}} k_0(x, k_{\hat\mu})$ always exists.

The *propagation cone* $K(\gamma, \Sigma_t)$ dual to $\Gamma(\gamma, \Sigma_t)$ is defined through $K(\gamma, \Sigma_t) := \{v \in T_x\mathcal{M} \mid k(v) \geq 0 \quad k \in T_x^*\mathcal{M}\} \subset T_x\mathcal{M}$. The boundary of K consists in those v for which $k(v) = 0$ for at least one $k \in \partial\Gamma$. Therefore for this k and v we have $k(v) = 0$ and $H(x,k) = 0$ from which, because of the smoothness of the normal cone, the relation

$$v^\mu = \frac{1}{m} \frac{\partial H(x,k)}{\partial k_\mu}\Big|_{k \in \partial\Gamma(\gamma, \Sigma_t)} \tag{3.6}$$

giving the *fastest signals* can be derived. Since $\frac{\partial}{\partial k_0} H(x,k) \neq 0$ the measured velocity $\dot{x}^{\hat\mu} = v^{\hat\mu}/v^0$ of the fastest signals is always finite. (3.5) is valid also for all $k \in N_x$ giving rise to the *bicharacteristics* resp. the *light rays*.

Here it will only be mentioned that with the above formalism we can define the notions of length, invariant volume-element, orthogonality, light-, time- and space-likeness and generalised Lorentz-transformations.

3.3. The geometry of the light rays

We now want to derive the equation of motion for the light rays starting from (3.4). Since $H(x,k)$ is homogeneous of degree m in the variable k we may get a Finslerian metric function (cf. Rund (1959)) by taking the mth root. However, we cannot proceed this way, because the indefiniteness of $H(x,k)$ makes it impossible to perform derivatives of the metric function. * We must therefore develop a generalised Finslerian formalism which starts from a function of arbitrary degree of homogeneity.

Taking the total derivative of (3.4) we get

$$0 = m v^\nu \partial_\nu k_\mu + \partial_\mu H(x,k). \tag{3.7}$$

* This corresponds to the fact that $0 = \delta \int ds$ in Riemannian geometry is defined only for $ds \neq 0$. However in the equation of motion the limit $ds \to 0$ can be carried out. For light rays one uses $0 = \delta \int (ds)^2$.

The difficulty now consists in expressing k through v which is possible only if (3.6) is solvable for k. To this end we define a (generalised) *Finslerian metric* in k homogeneous of degree $m-2$

$$g^{\mu\nu}(x,k) := \frac{1}{m(m-1)} \frac{\partial^2 H(x,k)}{\partial k_\mu \partial k_\nu} \tag{3.8}$$

and demand

Axiom 5: $\det\left(g^{\mu\nu}(x,k)\big|_{H(x,k)=0}\right) \neq 0.$

By means of the implicit function theorem this condition implies that on the normal cone the mapping (3.6) between k and v is one-to-one leading to a canonical isomorphism between the cotangent and the tangent space: $T_x^*(\mathcal{M}) \to T_x(\mathcal{M}) : k \mapsto v$. There is an inverse mapping $f : T_x(\mathcal{M}) \to T_x^*(\mathcal{M}) : v \mapsto k := f(x,v)$. The homogeneity of $H(x,k)$ implies $g^{\mu\nu}(x,k)k_\mu k_\nu = H(x,k)$ and $v^\mu = g^{\mu\nu}(x,k)k_\nu$. Defining the inverse metric $g_{\mu\nu}(x,v) := (m-1)\frac{\partial}{\partial v^\nu} f_\mu(x,v)$ it is not difficult to see that $\delta^\nu_\mu = g_{\mu\sigma}(x,v)g^{\sigma\nu}(x,k) = g_{\sigma\mu}(x,v)g^{\sigma\nu}(x,k)$ which implies that $g_{\mu\nu}(x,v)$ is also symmetric. Additionally, $\det(g_{\mu\nu}(x,v)) \neq 0$ and $k_\mu = g_{\mu\nu}(x,v)v^\nu$.

Geometrically the above condition leads to restrictions on the normal cone: one or two different components of the normal cone cannot intersect and the cone cannot be non-convex.

With these results it is now possible to extract from (3.7) the equation of motion for the light rays v:

$$0 = v^\nu \partial_\nu v^\mu + \left\{ {\mu \atop \nu\sigma} \right\}(x,v) v^\nu v^\sigma \tag{3.9}$$

with the generalised Finslerian transport coefficient

$$\left\{ {\mu \atop \nu\sigma} \right\}(x,v) := g^{\mu\rho}(x,f(x,v)) \left((m-1)\partial_{(\nu} g_{\sigma)\rho}(x,v) - \frac{(m-1)^2}{m} \partial_\rho g_{\sigma\nu}(x,v) \right)$$

which is homogeneous of degree zero in v. For $m=2$ it reduces to the usual Finslerian transport coefficient and for velocity independent metrics to the Christoffel-connection. Therefore, via (3.5) and the above equation of motion the light rays define a (generalised) *conformal Finslerian structure*. In general, for light rays the strong equivalence principle * is not valid.

Although $\left\{ {\mu \atop \nu\sigma} \right\}(x,v)$ constitutes no connection, we can obtain one by means of

$$\overset{\{\}}{\Gamma}{}^\sigma_{\mu\nu}(x,v) := \frac{1}{2} \frac{\partial^2}{\partial v^\mu \partial v^\nu} \left(\left\{ {\sigma \atop \tau\rho} \right\}(x,v) v^\tau v^\rho \right) \tag{3.10}$$

We remark that it is possible to set up a Lagrangian formulation with the Lagrange function $L(x,v) := H(x,f(x,v))$.

3.4. The characteristic Clifford-algebra

In this chapter we treat some general properties of the γ-matrices. They fulfill a characteristic Clifford-algebra first showing that the notion of a Clifford-algebra is intimately connected with the analysis of systems of partial differential equations, and second giving us a tool at hand to calculate the propagation of helicity states along the light-rays. Later (in ch. 4.3.) we shall derive the more specific generalised Clifford-algebra.

---

* A set of paths obeys the *strong equivalence principle* if there is a coordinate system and there are parametrisations so that for all paths the inertial law $\ddot{x} = 0$ holds.

For determining the characteristic Clifford-algebra the determinant of a matrix by means of multiplication can be represented by its minor B':

$$\prod_{r=1}^{R}\left(H^{(r)}(x,k)\right)^{\alpha_r} = H(x,k) = \det(\tilde{\gamma}^\mu k_\mu) = B'(x,k)\tilde{\gamma}^\mu k_\mu = \tilde{\gamma}^\mu k_\mu B'(x,k).$$

Since $\tilde{\gamma}^\mu k_\mu$ is Hermitian it is diagonalisable. Therefore there exists another matrix $B(x,k)$ so that

$$H_0(x,k) := \prod_{r=1}^{R} H^{(r)}(x,k) = B(x,k)\tilde{\gamma}^\mu k_\mu \tag{3.11}$$

with $H_0(x,k)$ being homogeneous of degree $m' := \sum m_r$ and possessing simple zeros only. Therefore no $H^{(r)}$ can possess a common zero with some other $H^{(r')}$. This shows that all normal cones, and therefore also all light cones, can intersect neither themselves nor one another.

$B(x,k)$ is homogeneous of degree $m'-1$ and has the form $B(x,k) = B^{\mu_1\cdots\mu_{m'-1}}$ $k_{\mu_1}\cdots k_{\mu_{m'-1}}$. Already equation (3.11) shows one of the most important features of a Clifford-algebra: that the product of matrices is proportional to the unit matrix. We obtain further features by differentiating this equation with respect to k

$$\left(\frac{\partial B}{\partial k_\mu}\right)\tilde{\gamma}^\nu k_\nu + B\tilde{\gamma}^\mu = \tilde{\gamma}^\nu k_\nu\left(\frac{\partial B}{\partial k_\mu}\right) + \tilde{\gamma}^\mu B = \frac{\partial H_0}{\partial k_\mu} =: m'V^\mu \sim v^\mu \tag{3.12}$$

$$\begin{aligned}\left(\frac{\partial^2 B}{\partial k_\mu \partial k_\nu}\right)\tilde{\gamma}^\sigma k_\sigma + 2\left(\frac{\partial B}{\partial k_{(\mu}}\right)\tilde{\gamma}^{\nu)} &= 2\tilde{\gamma}^{(\mu}\left(\frac{\partial B}{\partial k_{\nu)}}\right) + \tilde{\gamma}^\sigma k_\sigma\left(\frac{\partial^2 B}{\partial k_\mu \partial k_\nu}\right)\\ &= \frac{\partial^2 H_0}{\partial k_\mu \partial k_\nu} =: m'(m'-1)G^{\mu\nu}\end{aligned} \tag{3.13}$$

.....

$$m'\left(\frac{\partial^{m'-1}B}{\partial k_{(\mu_1}\cdots\partial k_{\mu_{m'-1}}}\right)\tilde{\gamma}^{\mu_{m'})} = m'\tilde{\gamma}^{(\mu_1}\left(\frac{\partial^{m'-1}B}{\partial k_{\mu_2}\cdots\partial k_{\mu_{m'})}}\right) = m'!G^{\mu_1\cdots\mu_{m'}} \tag{3.14}$$

The above equations (3.12 to 14) show most clearly the main feature of a Clifford algebra: it relates products of $\mathbf{C}^m$-valued matrices to space-time tensors. Equation (3.14) may be considered superior to all the other equations because the other equations may be derived from it. This equation, together with the explicit form of B, may be regarded as a Clifford algebra, which we will call a *characteristic Clifford algebra* because it is defined by means of the light cone:

$$B^{(\mu_1\cdots\mu_{m'-1}}\tilde{\gamma}^{\mu_{m'})} = \tilde{\gamma}^{(\mu_1}B^{\mu_2\cdots\mu_{m'})} = g_{m'}^{\mu_1\cdots\mu_{m'}}.$$

However, for our purposes the most important equations are (3.12) and (3.14) which connect the light-velocity and the metric with matrices acting on $\mathbf{C}^m$.

3.5. Propagation of helicity states

The singularities a are solutions of (3.1) whereby k is determined by (3.3), i.e. is a zero of one of the irreducible polynomials. The power α_r is the number of solutions a corresponding to one solution k. The a's are called *helicity states*. Since $a^+\tilde{\gamma}^\mu a \sim v^\mu$ these helicity states are also carrying information about the k's resp. the v's.

It is now our task to set up an equation of motion, a propagation law, for the a's, i.e. an equation of the form $v^\mu\partial_\mu a = v(a) \sim f(x,v,a)$ up to proportionality ((3.1) defines a only up to a factor). Thereby the function f shall depend on the values of v and a along the path of the light rays only. This can easily be done with the

help of the characteristic Clifford-algebra. Using (3.10) we get with some appropriate proportionality factor α ($\widetilde{M} := AM$):

$$\begin{aligned}\alpha v(a) &= \alpha \frac{1}{m'}\left(\frac{\partial H_0}{\partial k_\mu}\right)\partial_\mu^{\text{total}} a \\ &= \left(\frac{\partial B}{\partial k_\mu}\right)\tilde{\gamma}^\nu k_\nu \partial_\mu^{\text{total}} a + B\tilde{\gamma}^\mu \partial_\mu^{\text{total}} a \\ &= \left(\frac{\partial B}{\partial k_\mu}\right)\left[\partial_\mu^{\text{total}}(\tilde{\gamma}^\nu k_\nu a) - \partial_\mu^{\text{total}}(\tilde{\gamma}^\nu k_\nu)a\right] - B\left(\tilde{\gamma}^\nu k_\nu a^{(1)} + i\widetilde{M}a\right).\end{aligned}$$

The first term in the square bracket vanishes by virtue of (3.1) and the first term in the round bracket vanishes because of (3.11) so that, as far as a is concerned, we arrive at a propagation law

$$\alpha v(a) = -\left(\frac{\partial B}{\partial k_\mu}\right)\left[(\partial_\mu \tilde{\gamma}^\nu)k_\nu + \tilde{\gamma}^\nu \partial_\mu k_\nu\right] a - iB\widetilde{M}a.$$

However, the term $\partial_\mu k_\nu$ is not in order: it depends on k close by the path. It can be eliminated by means of (3.13) and the symmetry of $\partial_\mu k_\nu$: we insert $\frac{\partial B}{\partial k_{(\mu}}\tilde{\gamma}^{\nu)}$ and get

$$v(a) = -\frac{m'(m'-1)}{2\alpha}G^{\mu\nu}\partial_\mu k_\nu a - \frac{1}{\alpha}\left[\left(\frac{\partial B}{\partial k_\mu}\right)(\partial_\mu \tilde{\gamma}^\nu)k_\nu + iB\widetilde{M}\right] a \qquad (3.14).$$

In principle we arrived at our aim. Note that the 'mass' $\widetilde{M}$ enters the propagation law and - besides the metrical interaction - causes an additional rotation of the helicity states.

We can go further in showing that this equation can be written in a manifest covariant manner: to this end, we define a 'spinorial' connection through

$$0 = \left(\overset{\{\}}{D}_\mu \tilde{\gamma}^\nu\right) k_\nu := (\partial_\mu \tilde{\gamma}^\nu)k_\nu + \overset{\{\}}{\Gamma}{}^\sigma_{\mu\nu}(x,k)\tilde{\gamma}^\nu k_\sigma + \left[\overset{\{\}}{\Gamma}_\mu(x,k), \tilde{\gamma}^\nu k_\nu\right] \qquad (3.15)$$

which are $4m^2$ equations for the $4m^2$ unknown $\overset{\{\}}{\Gamma}_\mu(x,k)$. The vector connection is obtained from (3.9) and v is replaced by k. Inserting (3.15) into (3.14) and using (3.11) and (3.12) we finally get

$$v^\mu \overset{\{\}}{D}_\mu a = \frac{1}{\alpha}\left[\frac{m'(m'-1)}{2}G^{\mu\nu}\overset{\{\}}{D}_\mu k_\nu + B\left(\tilde{\gamma}^\mu \overset{\{\}}{\Gamma}_\mu - iM\right)\right] a \qquad (3.16)$$

which represents a manifest covariant transportation law for the direction of a. Here we defined $\overset{\{\}}{D}_\mu(x,v)a := \partial_\mu a + \overset{\{\}}{\Gamma}_\mu(x,v)a$ and $\overset{\{\}}{D}_\mu k_\nu := \partial_\mu k_\nu - \overset{\{\}}{\Gamma}{}^\sigma_{\mu\nu}(x,k)k_\sigma$.

By means of the above transportation law the underlying geometry may be described. This will be undertaken in ch. 5 where a special case will be discussed.

4. The classical limit: path structure and spin-propagation

In this chapter a new structure, the classical limit of the field equation (2.13), will be introduced. This amounts to a theory bearing some similarities to that outlined in the preceding chapter, so that some of the already developed ideas can now be taken over and represented in shorter form. While the former theory was a definite mathematical feature of partial differential equations, the classical limit which postulates that plane waves are approximate solutions of (2.13), is valid in certain physical situations only.

The geometrical structure we arrive at will be even more general than the Finslerian: the basic metric function, resp. the Hamilton function, will be some non-homogeneous polynomial in the momenta. With this Hamilton function we can describe mass shells and the paths of the 'classical' particles as well as the propagation of spin states. Again, the paths are related to the metrical structure of space-time while the propagation of the WKB-states gives some affine structure. In the high-energy-limit the particle velocity approaches the light velocity, while the paths of the classical particles may yet be different from the light rays - thereby showing that kinematically though not necessarily dynamically the geometry induced by the singularities is contained in the classical limit. Since the classical limit shows more features than the singularities it is now possible to derive the full generalised Clifford-algebra which (i) again is essential in deriving the propagation of WKB-states, (ii) also connects space-time tensors with the γ-matrices and (iii) gives the principle underlying the linearisation of higher order scalar partial differential equations.

4.1. The classical limit

The classical limit, or WKB-limit, describes situations where there exist solutions of (2.13) which are approximately, that is within a certain sufficently small region, plane waves.

Definition: *$\varphi : \mathcal{M} \to \mathbf{C}^m$ is a local plane wave if within an appropriate neighbourhood of $x \in \mathcal{M}$ there is a field of $\mathbf{C}^m$-bases and functions $S \in \mathrm{C}^2(\mathcal{M}, \mathbf{R})$ and $a \in \mathrm{C}^1(\mathcal{M}, \mathbf{C}^m)$ so that it can be represented as*

$$\varphi(x) = a(x)e^{iS(x)} \tag{4.1}$$

with * $\|i\gamma^\mu \partial_\mu a\| \ll \|a\|$ *if a is represented with respect to the field of $\mathbf{C}^m$-bases.*

A transformation $\varphi \to \varphi' := S\varphi$ which leaves $\|a\|$ invariant changes the above estimate to

$$\|i\tilde{\gamma}^\mu \partial_\mu a' - M^{(1)\prime} a'\| \ll \|a'\| \tag{4.2}$$

with $\left(M^{(1)}\right)' := i\tilde{\gamma}'^\mu S \partial_\mu S^{-1}$. This means that the existence of local plane waves distinguishes a special class of base fields and therefore induces the existence of a matrix $M^{(1)}$ transforming according to $M^{(1)} \to \left(M^{(1)}\right)' = SM^{(1)}S^{-1} - i\tilde{\gamma}'^\mu S \partial_\mu S^{-1}$, that is, like M. Of course, $M^{(1)}$ like M is no connection, but shares some features of it. $M^{(1)}$ is defined only up to matrices annihilating a. With the help of this matrix the covariance of the estimate (4.2) can be maintained.

A constant *active* transformation of a leaving $\|a\|$ invariant gives a new local plane wave solution.

Note that our classical limit is no expansion with respect to $\hbar$, because a field equation like (2.13) by itself does not define any such quantity.

---

* $\|a\| := a^+ \tilde{\gamma}^\mu n_\mu a$ with $n_\mu = \partial_\mu \Sigma_t$.

Now we are looking for equations which must be valid if (2.13) will admit local plane waves. Inserting (4.1) into the field equation we get with $M^{(0)} := M - M^{(1)}$ which transforms homogeneously, and the *momentum* $p_\mu := -\partial_\mu S$

$$0 = \left(\tilde{\gamma}^\mu p_\mu - M^{(0)}\right) a + i\tilde{\gamma}^\mu \partial_\mu a - M^{(1)} a.$$

If (4.1) is a local plane wave solution, then the second term can be neglected so that the first term, the term of lowest order, vanishes. Therefore the other term, determining the derivative of those solutions, also has to vanish. Therefore, as equations describing local plane waves, the WKB-equations we get

$$0 = \left(\tilde{\gamma}^\mu p_\mu - M^{(0)}\right) a \tag{4.3}$$

$$0 = i\tilde{\gamma}^\mu \partial_\mu a - M^{(1)} a. \tag{4.4}$$

We show now that the 'mass' $M^{(0)}$ is Hermitian: The current conservation (2.15) together with (2.13) implies $0 = \partial_\mu(\varphi^+ \tilde{\gamma}^\mu \varphi) = \varphi^+ \left(i(AM)^+ - iAM + \partial_\mu \tilde{\gamma}^\mu\right) \varphi$. Since this is true for all $\varphi(x)$ (axiom 1(i)) we conclude $0 = i(AM)^+ - iAM + \partial_\mu \tilde{\gamma}^\mu$. On the other hand, $\varphi^+ \tilde{\gamma}^\mu \varphi = a^+ \tilde{\gamma}^\mu a$ so that with the help of (4.4) we get $0 = \partial_\mu(a^+ \tilde{\gamma}^\mu a) = a^+ \left(i(AM^{(1)})^+ - iAM^{(1)} + \partial_\mu \tilde{\gamma}^\mu\right) a$. Comparison gives $a^+ \left((AM^{(0)})^+ - AM^{(0)}\right) a = 0$ for all a so that $\left(AM^{(0)}\right)^+ = AM^{(0)}$.

It is clear that (4.3) can be brought to the form

$$0 = \left(\tilde{\gamma}^\mu p_\mu - \bar{E}\right) a \tag{4.5}$$

where $\bar{E}$ is a unit matrix up to some diagonal zeros according to the rank of $M^{(0)}$ and that there is another Hermitian matrix $\bar{\beta}$ which hermitises $\tilde{\gamma}$: $(\tilde{\gamma}^\mu)^+ = \bar{\beta}\tilde{\gamma}^\mu \bar{\beta}^{-1}$.

4.2. The geometry of the mass shell

For WKB-solutions to exist, equation (4.3 resp. 5) must have nontrivial solutions. This is possible only if the coefficient matrix fulfills as solvability condition the *Hamilton-Jacobi equation*

$$0 = \det\left(\tilde{\gamma}^\mu p_\mu - \bar{E}\right) =: \sum_{i=1}^{m} \bar{g}_i(p, \ldots, p) - \bar{\epsilon} =: H_c(x,p), \quad \bar{\epsilon} := \begin{cases} 0 & \text{if } \det M^{(0)} = 0 \\ 1 & \text{if } \det M^{(0)} = 1. \end{cases} \tag{4.6}$$

Again this is one real equation defining m totally symmetric $C^\infty(\mathcal{M})$-tensor fields $\bar{g}_i$. For each given $p_{\hat{\mu}}$ there are m solutions $p_0 = p_0(x, p_{\hat{\mu}})$ of (4.6). Of course $H_c = H + Q$ for some polynomial Q of degree lower than m. From the Laplace expansion theorem for determinants it is clear that

$$\bar{g}_1^\mu = (-1)^m \operatorname{tr}\tilde{\gamma}^\mu, \qquad \bar{g}_2^{\mu\nu} = \tfrac{1}{2}(-1)^{m-1}\left(\operatorname{tr}\tilde{\gamma}^\mu \operatorname{tr}\tilde{\gamma}^\nu - \operatorname{tr}(\tilde{\gamma}^\mu \tilde{\gamma}^\nu)\right).$$

In general $H_c(x,p)$ consists of a product of irreducible polynomials $H_c(x,p) = \prod_{r=1}^{R} \left(H_c^{(r)}(x,p)\right)^{\alpha_r}$ with $\sum_{r=1}^{R} m_r \alpha_r = m$. Each $H_c^{(r)}(x,p)$ possesses m_r solutions. The *mass shell* at $x \in \mathcal{M}$ is $S := \{p \in T_x^* \mathcal{M} \mid H_c(x,p) = 0\}$. In the following we will consider one equation $H^{(r)}(x,p) = 0$ only and drop the index (r).

(4.6) represents a Hamilton-Jacobi differential equation for the phase $S(x)$. It always possesses a solution because $\dfrac{\partial}{\partial p_0} H(x,p) \neq 0$ which again results from the fact that $H(x,p) = 0$ possesses simple zeros only. This can be established with the same

argument as in the case of the normal cone. Also, since the above derivative does not vanish, $p_0(x, p_{\hat{\mu}})$ is locally analytical. Therefore the derivative $\frac{\partial}{\partial p_{\hat{\mu}}} p_0(x, p_{\hat{\mu}})$ exists so that the vector

$$\bar{v}_c^\mu(x,p) := \frac{1}{m}\frac{\partial H_c(x,p)}{\partial p_\mu}\Big|_{H_c(x,p)=0}$$

can be interpreted as *group velocity* of a wave packet. Of course $\lim_{p_{\hat{\mu}}\to\infty} \bar{v}_c = v$.

4.3. The path structure

We now want to derive the equation of motion for the group velocity starting from (4.6). Taking the total derivative we again get $0 = m\bar{v}_c^\nu \partial_\nu p_\mu + \partial_\mu H_c(x,p)$. Again we define $\bar{g}_c^{\mu\nu}(x,p) := \frac{1}{m(m-1)}\frac{\partial^2 H_c(x,p)}{\partial p_\mu \partial p_\nu}$ and have to demand

Axiom 6: $\det\left(\bar{g}_c^{\mu\nu}(x,k)\big|_{H_c(x,k)=0}\right) \neq 0.$

Therefore the mapping $p \to \bar{v}_c$ is an isomorphism and there is an inverse mapping $\bar{f}_c : \bar{v}_c \to p$. We also define $\bar{g}_{c\mu\nu}(x,\bar{v}_c) := (m-1)\frac{\partial}{\partial \bar{v}_c^\nu}\bar{f}_{c\mu}(x,\bar{v}_c)$ and can show that $\bar{g}_{c\mu\nu}(x,\bar{v}_c)$ is symmetric too. *

Defining $L_c(x,\bar{v}) := H_c(x,\bar{f}(x,\bar{v}))$ we get after some calculation the equation of motion for the group velocity

$$\bar{v}_c^\nu \partial_\nu \bar{v}_c^\mu + \overset{()}{\bar{G}}{}^\mu(x,\bar{v}_c) = 0 \tag{4.7}$$

with $\overset{()}{\bar{G}}{}^\mu(x,\bar{v}_c) := (m-1)\bar{g}_c^{\mu\nu}(x,\bar{f}_c(x,\bar{v}_c))\left(2\bar{v}_c^\sigma \partial_{[\sigma}\bar{f}_{c\nu]}(x,\bar{v}_c) + \frac{1}{m}\partial_\nu L_c(x,\bar{v}_c)\right)$. For $m = 2$ and $\bar{g}_1 = 0$ it reduces to the usual Riemannian geodesic equation and for $\bar{g}_i = 0, i = 1,\ldots,m-1$ to (3.9). For this path structure the strong equivalence principle in general does not hold.

In general for $p_{\hat{\mu}} \to \infty$ (4.7) does not approach (3.9) showing that null geodesics do not necessarily fill out the whole light cone.

For a later purpose it is convenient to perform a transformation on the momenta in such a way that in the resulting function $\mathcal{H}$ the linear term vanishes. To this end we define the *kinematical momentum* $P := p - A$ with $A(x) := \bar{f}_c(x,0)$. Then we have

$$'\mathcal{H}_c(x,P) := H_c(x,P+A) = \sum_{i=0}^{m} {}'g_i(P,\ldots,P) \tag{4.8}$$

with $'g_1 = 0$. In the case of $\mathcal{H}_c(x,A) \neq 0$ (4.8) may be divided through $-'\mathcal{H}_c(x,A)$ to get

$$\mathcal{H}_c(x,P) = \sum_{i=2}^{m} g_i(P,\ldots,P) - \epsilon \quad \text{with} \quad \epsilon = \begin{cases} 1 & \text{if } '\mathcal{H}_c(x,A) \neq 0 \\ 0 & \text{if } '\mathcal{H}_c(x,A) = 0 \end{cases} \tag{4.9}$$

with renormalised coefficients g_i of which g_1 vanishes. We can again define the velocity v_c and the metric g_c in analogy to $\bar{v}_c$ and $\bar{g}_c$. It is $v_c = \bar{v}_c$ and $g_c = \bar{g}_c$. These equalities and the fact that $v_c = 0$ for $P = 0$ justifies calling P the kinematical momentum.

---

* The relations for the light rays arising from the homogeneity of the function H are in general not valid in this case.

For this Hamilton function the above formalism is valid mutatis mutandis: From (4.9) the equation of motion can also be derived:

$$0 = v_c^\nu \partial_\nu v_c^\mu + \overset{\{\}}{G}{}^\mu(x, v_c) + g_c^{\mu\nu}(x, f(x, v_c)) F_{\nu\sigma} v_c^\sigma .$$

with $F_{\nu\sigma} := -\partial_\mu A_\sigma + \partial_\sigma A_\mu$. Later we interpret $F_{\nu\sigma}$ as Maxwell field. We will call the formalism resting on $\mathcal{H}(x, P)$ the *kinematical formalism*.

4.4. The generalised Clifford algebra

In this section we want to examine the properties of the γ-matrices in their totality. This will lead to the notion of a generalised Clifford algebra which is useful for the same purposes as the characteristic Clifford algebra, that is, for the calculation of a propagation law of the WKB-states. It additionally allows discussion of the linearisation of scalar wave equations of higher order.

In analogy to ch. 3.3. we are here dealing with the algebra corresponding to the solvability condition (4.6). The formalism is absolutely the same except that the matrix $\bar{B}(x, p)$ is now not homogeneous:

$$\bar{B}(x, p) = \sum_{i=1}^{m'-1} \bar{B}^{\mu_1, \mu_2, \ldots, \mu_i}(x) p_{\mu_1} p_{\mu_2} \cdots p_{\mu_i} .$$

Again we have

$$\bar{B}(x, p) \left(\bar{\gamma}^\mu p_\mu - \bar{E}\right) = \left(\bar{\gamma}^\mu p_\mu - \bar{E}\right) \bar{B}(x, p) = H_{c0}(x, p) = \sum_{i=1}^{m'} \bar{g}_i(p, \ldots, p) - \bar{\epsilon} \quad (4.10)$$

with a H_{c0} possessing simple zeros only.

Differentiation of (4.10) with respect to p gives

$$\left(\frac{\partial \bar{B}}{\partial p_\mu}\right)(\bar{\gamma}^\nu p_\nu - \bar{E}) + \bar{B}\bar{\gamma}^\mu = (\bar{\gamma}^\nu p_\nu - \bar{E})\left(\frac{\partial \bar{B}}{\partial p_\mu}\right) + \bar{\gamma}^\mu \bar{B} = \frac{\partial H_{c0}}{\partial p_\mu} =: m' V^\mu \sim v_c^\mu \quad (4.11)$$

$$\begin{aligned}\left(\frac{\partial^2 \bar{B}}{\partial p_\mu \partial p_\nu}\right)(\bar{\gamma}^\sigma k_\sigma - \bar{E}) + 2\left(\frac{\partial \bar{B}}{\partial p_{(\mu}}\right)\bar{\gamma}^{\nu)} &= 2\bar{\gamma}^{(\mu}\left(\frac{\partial \bar{B}}{\partial p_{\nu)}}\right) + (\bar{\gamma}^\sigma k_\sigma - \bar{E})\left(\frac{\partial^2 \bar{B}}{\partial p_\mu \partial p_\nu}\right) \\ &= \frac{\partial^2 H_{c0}}{\partial p_\mu \partial p_\nu} =: m'(m'-1)\bar{G}^{\mu\nu}\end{aligned} \quad (4.12)$$

$$\cdots \cdots \cdots \cdots$$

$$m'\left(\frac{\partial^{m'-1} \bar{B}}{\partial p_{(\mu_1} \cdots \partial p_{\mu_{m'-1}}}\right)\bar{\gamma}^{\mu_{m'})} = m'\bar{\gamma}^{(\mu_1}\left(\frac{\partial^{m'-1} \bar{B}}{\partial p_{\mu_2} \cdots \partial p_{\mu_{m'})}}\right) = m'! g_{m'}^{\mu_1, \ldots, \mu_{m'}} . \quad (4.13)$$

The last equation was also arrived at by dealing with the characteristic Clifford-algebra. Beside this series of equations, we can insert (4.10) into (4.9). In order that the resulting equation is fulfilled for all p each coefficient has to vanish. We get

$$\begin{aligned} -\bar{B}^0 \bar{E} = -\bar{E}\bar{B}^0 &= -1 \\ \bar{B}^0 \bar{\gamma}^\mu - \bar{B}^\mu \bar{E} = \bar{\gamma}^\mu \bar{B}^0 - \bar{E}\bar{B}^\mu &= \bar{g}_c^\mu \\ \bar{B}^{(\mu}\bar{\gamma}^{\nu)} - \bar{B}^{\mu\nu}\bar{E} = \bar{\gamma}^{(\mu}\bar{B}^{\nu)} - \bar{E}\bar{B}^{\mu\nu} &= \bar{g}_2^{\mu\nu} \\ &\cdots\cdots \\ \bar{B}^{(\mu_1, \mu_2, \ldots, \mu_{m'-1}}\bar{\gamma}^{\mu_{m'})} = \bar{\gamma}^{(\mu_1}\bar{B}^{\mu_2, \ldots, \mu_{m'-1}, \mu_{m'})} &= \bar{g}_{m'}^{\mu_1, \ldots, \mu_{m'}} . \end{aligned} \quad (4.14)$$

For $E = 1$ this system of equations can now be successively solved for $\bar{B}^{\mu_1,\mu_2,\ldots,\mu_{m'}}$:

$$\begin{aligned}
\bar{B}^0 &= 1 \\
\bar{B}^\mu &= \bar{\gamma}^\mu - \bar{g}_1^\mu \\
\bar{B}^{\mu\nu} &= \bar{\gamma}^{(\mu}\bar{\gamma}^{\nu)} - \bar{\gamma}^{(\mu}\bar{g}_1^{\nu)} - \bar{g}_2^{\mu\nu} \\
&\ldots\ldots\ldots\ldots\ldots\ldots \\
\bar{B}^{(\mu_1,\mu_2,\ldots,\mu_{m'-1})} &= \sum_{j=0}^{m'} \bar{\gamma}^{(\mu_1}\ldots\bar{\gamma}^{\mu_j}\left(-\bar{g}_{m'-j}^{\mu_{j+1}\ldots\mu_{m'-1}}\right)
\end{aligned}$$

However $\bar{B}^{(\mu_1,\mu_2,\ldots,\mu_{m'-1})}$ has to fulfill (4.14) giving a relation which we will call a *generalised Clifford-algebra*:

$$0 = \sum_{i=0}^{m'} \bar{\gamma}^{(\mu_1}\ldots\bar{\gamma}^{\mu_i}\left(-\bar{g}_{m'-j}^{\mu_{i+1}\ldots\mu_{m'})}\right). \tag{4.15}$$

This equation relates the metrical coefficients $\bar{g}_i$ to the $\bar{\gamma}$-matrices. Assuming the special case $\bar{g}_i = 0$ for $i = 1,\ldots,m'-1$ we get $\bar{g}_{m'}^{\mu_1,\ldots,\mu_{m'}} = \bar{\gamma}^{(\mu_1}\ldots\bar{\gamma}^{\mu_{m'})}$ which already was considered by Nono (1971) in a different context.

The above relations are valid mutatis mutandis in the kinematical formalism: replacing in (4.3) p by $P + A$ we get $0 = \left(\bar{\gamma}^\mu P_\mu - M_A^{(0)}\right)a$ with the new 'mass' $M_A^{(0)} := M^{(0)} - \bar{\gamma}^\mu A_\mu$. With the same reasoning as below (4.4) we arrive at an equation $0 = (\gamma^\mu P_\mu - E)\,a$ together with an Hermitising matrix β: $(\gamma^\mu)^+ = \beta\gamma^\mu\beta^{-1}$. Of course $\mathrm{tr}\gamma^\mu = 0$.

4.5. Propagation of the spin states

The *spin states* a are solutions of (4.5) whereby for one given p as solution of (4.6) many a's may occure according to the multiplicity of the zero. For each two solutions belonging to one p we get for an arbitrary matrix Q

$$\begin{aligned}
0 &= \bar{a}Q\left(\bar{\gamma}^\mu p_\mu - \bar{E}\right)a \\
0 &= \bar{a}\left(\bar{\gamma}^\mu p_\mu - \bar{E}\right)Qa
\end{aligned}$$

with $\bar{a} := a^+\bar{\beta}$. Addition and subtraction of these equations gives

$$(\bar{a}\{Q,\bar{\gamma}^\mu\}a)\,p_\mu = 2\bar{a}Qa \tag{4.16}$$

$$(\bar{a}[Q,\bar{\gamma}^\mu]a)\,p_\mu = 0 \tag{4.17}$$

The remainder of this chapter is completely analogous to ch. 3.5. It is a matter of replacing H_0, (3.4), helicity-states, (3.11 and 12) by $\bar{H}_{c0}$, (4.6), spin-states, (4.11 and 12). For the equation of motion of the spin states we get

$$v^\mu \overset{\Gamma}{D}_\mu a = \frac{1}{\alpha}\left[-\frac{m'(m'-1)}{2}\bar{G}^{\mu\nu}\overset{\Gamma}{D}_\mu p_\nu + B\left(\bar{\gamma}^\mu\bar{\Gamma}_\mu - iM^{(1)}\right)\right]a \tag{4.18}$$

with the definition

$$0 = \left(\overset{\Gamma}{D}_\mu\bar{\gamma}^\nu\right)p_\nu = (\partial_\mu\bar{\gamma}^\nu)\,p_\nu + \bar{\Gamma}^\nu_{\mu\sigma}(x,p)\bar{\gamma}^\sigma p_\nu + \left[\bar{\Gamma}_\mu(x,p),\bar{\gamma}^\nu p_\nu\right]$$

whereby the $\tilde{\Gamma}^{\nu}_{\mu\sigma}(x,p)$ was obtained from $\overset{()}{\tilde{G}}(x,\tilde{v}_c)$ according to (3.10).

In the kinematical formalism (4.18) remains unchanged but the bars are omitted and an extra term $\frac{1}{2}F_{\mu\nu}\frac{\partial B}{\partial P_{[\mu}}\gamma^{\nu]}$ appears.

After these general considerations we can now further specify the field equation to arrive at the usual Dirac equation and discover its geometry.

5. The Dirac equation

In this chapter we want to find some minimal requirements in order to arrive at, resp. to characterise the usual Dirac equation. These demands essentially consist in two internal degrees of freedom for the helicity and spin states and two light cones and one time-like group velocity. Subsequently the most general Hamilton-Jacobi equation for the classical limit meeting these demands can be set up and discussed. The equation of motion for the paths turns out to be the Lorentz force equation in a Riemannian space-time. With the help of the propagation of the WKB-states the bilinear forms can be studied further. Since we are led to the usual Clifford-algebra more specific results can be concluded than in the general case. As the main result of this work, the propagation of the bilinear forms will define a Riemann-Cartan space-time with axial torsion only and a Maxwell field with which they interact via the usual coupling terms and a non-minimal Pauli term as well.

5.1. The propagation of singularities

Up to now, in nature never more than two light cones (one future and one past cone) have been observed to exist in 'empty space' (for a careful analysis of experimental data cf. Bleyer (1988).) In addition, there should be no more than two helicity states:

Axiom 7:
(i) *There are two light cones only.*
(ii) *There are two helicity states.*

As there are two helicity states on the light cone, the multiplicity of the zeros of the characteristic polynomial is two, so that the characteristic polynomial is the square of another one: $H(x,k) = (H_0(x,k))^2$. Furthermore, H_0 shall lead to two light cones only, being therefore a polynomial of order two: $H_0(x,k) = g^{\mu\nu}(x)k_\mu k_\nu$. As the characteristic polynomial is of order four, the γ's and the M are complex-valued 4×4-matrices.

It is clear that the metrical structure is given by the tensor $g^{\mu\nu}(x)$ with $\det g^{\mu\nu}(x) \neq 0$ so that there is an inverse $g_{\mu\nu}(x)$. These metrical tensors define a *conformal structure*. The light rays are given by $v^\mu = g^{\mu\nu}k_\nu$. The equation of motion for these light rays is the usual geodesic equation with the Christoffel symbols made up of the $g^{\mu\nu}$. It is clear from the hyperbolicity of H that the metric $g^{\mu\nu}$ has the correct signature.

The characteristic Clifford-algebra is given by a matrix $B = B^\mu p_\mu$ obeying $B^{(\mu}\tilde{\gamma}^{\nu)} = g^{\mu\nu}$. The helicity states obey the following propagation equation $v^\mu \overset{()}{D}_\mu a = -\frac{1}{2}g^{\mu\nu}\overset{()}{D}_\mu k_\nu a + \frac{1}{2}B\left(\tilde{\gamma}^\nu \overset{()}{\Gamma}_\nu - M^{(1)}\right)a$.

5.2. The classical limit

Since in the Hamilton-Jacobi-equation the square of $H(x,k)$ appears as highest order part, the Hamilton-Jacobi-equation must be of the form $H_c(x,p) = (g^{\mu\nu}(x)k_\mu k_\nu)^2 +$

$\bar{g}_3^{\mu\nu\sigma}(x)k_\mu k_\nu k_\sigma + \bar{g}_2^{\mu\nu}(x)k_\mu k_\nu + \bar{g}_1^{\mu}(x)k_\mu - \bar{c}$. We take as a further basic experience and demand towards a characterisation of the Dirac-equation:

Axiom 8:
(i) *There are two spin states.*
(ii) *There is a time-like group velocity.*

As the equation of motion for the spin-states we get

$$v_c^\mu \overset{0}{D}_\mu a = -\tfrac{1}{2} g^{\mu\nu} \left(\overset{0}{D}_\mu P_\nu \right) a + \tfrac{1}{2} \left(\gamma^\nu P_\nu + 1 \right) K a - \tfrac{1}{2} F_{\mu\nu} \gamma^\mu \gamma^\nu$$

with $K := \frac{1}{2}\left(\gamma^\mu \Gamma_\mu - iM^{(1)}\right)$ which is an arbitrary matrix.

A tedious calculation now gives the propagation laws for the bilinear forms whereby each derivative of one bilinear form depends on all the other bilinear forms. Since in all propagation laws there is an open proportionality factor, and because of (5.2) we can restrict ourselves to the normalised current vector, which however is identical to the particle velocity, and to the normalised *spin-vector* $\widehat{S}^\mu := \frac{1}{S} S^\mu$, so that the only independent entities are now v_c and $\widehat{S}$. Of course, the propagation equation for the current is equivalent to the previously derived equation (5.1).

More calculation then implies that

$$v_c^\nu \overset{0}{D}_\nu \widehat{S}^\mu = -g^{\mu\nu} \left(F_{\nu\sigma} + K_{[\nu\sigma]} \right) \widehat{S}^\sigma + v_c^\nu \epsilon_{\nu\rho}{}^{\mu\sigma} K_\sigma \widehat{S}^\rho + v_c^\mu K_{[\nu\sigma]} v_c^\nu \widehat{S}^\sigma. \qquad (5.3)$$

The tensor $K_{[\mu\nu]}$ and axial vector K_μ result from the arbitrary matrix K. However, not all degrees of freedom of the matrix K survive.

The first term on the right hand side of (5.3) is the spin precession in the electromagnetic field. The term with K_σ can be identified with a connection-term which has the form of an axial torsion (For a survey of space-time theories with torsion see Baekler, Hehl and Mielke (1986)).

However, beside the Maxwell field no other field has been observed to cause the precession of the spin so that we state the last axiom:

Axiom 9: *The spin precession is always proportional to the Maxwell field.*

This requirement implies $K_{[\mu\nu]} = \alpha F_{[\mu\nu]}$ for some coefficient α. Defining the anomalous gyromagnetic ratio $g := 2(1+\alpha)$ we get as final propagation equation

$$v_c^\nu \overset{*}{D}_\nu \widehat{S}^\mu = -\frac{g}{2} g^{\mu\nu} F_{\nu\sigma} \widehat{S}^\sigma + \left(\frac{g}{2} - 1 \right) v_c^\mu F_{[\nu\sigma]} v_c^\nu \widehat{S}^\sigma \qquad (5.4)$$

whereby $\overset{*}{D}$ is the covariant derivative with the axial torsion. This equation is the BMT-equation (see Bargmann, Michel and Telegdi (1959), Rubinov and Keller (1963) and Rafanelli and Schiller (1964)) in a Riemann-Cartan space (cf. Audretsch (1981), (1981a)).

Because of the last equation we can state the following result; that the Dirac equation which has been characterised by means of the axioms 1 to 9 indeed *defines as geometry a Riemann-Cartan geometry with axial torsion.* In addition, a *Maxwell field couples to the Dirac particles in the classical limit via charge and anamalous magnetic moment.*

Acknowledgement

This work forms part of the author's thesis written under the direction of Prof. J. Audretsch to whom I am grateful for encouragement and support. For discussions I thank Prof. H. Dehnen, Dipl.-Phys. D. Kovacs and especially Prof. W. Watzlawek, who was most helpful and referred me to some useful literature.

Austin, Texas 78712-1081

I. FORMALISM FOR QUANTUM MECHANICS: PATH INTEGRATION

It is customary, nowadays, to pay homage to path integration at the beginning of a course in Quantum Physics—but later on to use only its most obvious properties. So much so that it is often said that,

> "Feynman path integrals are mathematically meaningless."
>
> "We only know how to integrate gaussian path integrals."
>
> "A path integral is only the solution of a parabolic partial differential equation, satisfying some initial conditions."

I hope that my brief presentation will show that none of the above is true. I shall refute these three statements while summarizing works where

Feynman path integrals are defined;
path integrals are computed;
path integrals appear in varied situations.

I will then have in hand an excellent tool to study quantum mechanics in curved spacetimes—a tool to solve problems and an "instrument de pensée".

A. Defining Feynman path integrals (as opposed to Wiener integrals)

A path integral I is an integral over a space of paths X. A path $x \in X$ is a map

$$x : T \times \Omega \to M \qquad \text{by} \qquad x(t, \omega) \in M \ .$$

[1] "When dealing with less simple and concrete equations, physical intuition is less reliable and often borders on wishful thinking" (van Kampen, 1976).

Quantum Mechanics in Curved Space-Time
Edited by J. Audretsch and V. de Sabbata
Plenum Press, New York, 1990

A point $\omega \in \Omega$ labels a path, t parametrizes the path $x(\cdot, \omega)$. M can be a Riemannian manifold, a multiply connected space, a μ-sheeted Riemann surface, a group manifold, or a symmetric space. To begin with, M will be $\mathbb{R}^n$.

$$I = \int_\Omega F\big(x(t,\omega)\big)\, d\mu(\omega) \ . \tag{I.A–1}$$

μ is an integrator—possibly a measure; $F : M \to \mathbb{R}$.

The space of paths X is, in general, infinite-dimensional, and our intuition based on the properties of $\mathbb{R}^n$ can lead us astray[1] if we think of the path integral I as the limit when $n = \infty$ of an integral over $\mathbb{R}^n$ [see DeWitt-Morette et al., 1979, Appendix A, for some differences between integration over $\mathbb{R}^n$ and functional integration]. Leaving our intuition aside, we can learn functional integration from mathematicians. But most mathematicians have developed functional integration with a restriction that precludes its uses in Feynman path integrals. Namely, the integral is over a probability space $(\Omega, \mathcal{F}, \mu)$ where $\mathcal{F}$ is a σ-algebra of subsets of Ω and μ a bounded measure on $\mathcal{F}$, normalized to unity

$$\mu(\Omega) = 1 \ . \tag{I.A–2}$$

Feynman path integrals are not sums of probabilities but sums of probability amplitudes expressible in terms of unbounded measures. And already on $\mathbb{R}^n$ for $n \geq 2$, most of integration theory is cast in terms of bounded measures.

Dyson calls the mathematical definition of Feynman integrals over spaces of paths and over spaces of histories an "opportunity" not to be missed. Several approaches have been investigated for making mathematical sense of Feynman integrals. See the Appendix.

These different approaches serve different purposes. Many of them aim at defining path integrals for as large a class of physical systems as possible. I will present one of them, the prodistribution definition, because it leads to computational techniques that have effectively been used to solve problems of quantum mechanics in curved spacetimes. For example, to quote a nontrivial problem, the calculation of glory scattering of polarized waves by black holes can be expressed in terms of the solution of an associated system—and this associated system is the quantum mechanics of particles moving in curved spacetimes (DeWitt-Morette, 1984). The cross section obtained from path integrals defined and computed with prodistributions is

$$d\sigma(\Omega)/d\Omega = 4\pi^2 \lambda^{-1} B^2(\theta) \frac{dB(\theta)}{d\theta} J_{2s}^2\big(2\pi\lambda^{-1} B(\theta) \sin\theta\big) \tag{I.A–3}$$

where Ω is the solid angle $d\Omega = 2\pi \sin\theta\, d\theta$, λ is the wave length of the scattered wave, $B(\theta)$ is the inverse of the deflection function $\Theta(B)$, giving the scattering angle θ of a ray as a function of its impact parameter B. For example, for a Schwartzschild black hole of mass M (Darwin, 1959)

$$B(\theta) = M\big(3\sqrt{3} + 3.48 \exp(-\theta)\big) \ . \tag{I.A–4}$$

J_{2s} is the Bessel function of order $2s$ with $s = 0$ for a scalar wave, $s = 1$ for an electromagnetic wave, $s = 2$ for a gravitational wave. This formula matches

perfectly with the Handler-Matzner numerical calculations based on partial wave decomposition (Futterman et al., 1988).

I refer you to DeWitt-Morette (1984) for the complete detailed calculation of the glory cross section (I.A–3). Here I give only the building blocks; first the definition of a prodistribution; then, in Section I.B, a computational technique based on this definition.

A number of years ago, at the suggestion of Yvonne Choquet-Bruhat, I found in the chapter of Bourbaki on integration on topological vector spaces (Bourbaki, 1969) the means of defining an object, which could be used to build and compute some Feynman integrals. Whereas most texts on probability begin with $(\Omega, \mathcal{F}, \mu_{\mathcal{F}})$, a set Ω, a Borel σ-algebra $\mathcal{F}$, a measure $\mu_{\mathcal{F}}$ on $\mathcal{F}$, Bourbaki begins with $(\Omega, \mathcal{Q}, \mu_{\mathcal{Q}})$, a topological vector space Ω Hausdorff and locally convex, a projective family of finite-dimensional spaces $\mathcal{Q}$ related to Ω and a *pro*jective family of bounded *measures* $\mu_{\mathcal{Q}}$ on $\mathcal{Q}$, called "promeasures".

A projective family of finite-dimensional spaces is a mathematical construction, which accounts for Feynman's heuristic procedure. It states qualitatively the idea, "Let us replace a path by an arbitrary finite set of its values"; it makes it simple to ensure that the result is independent of the chosen set. But it does more because the finite-dimensional spaces are not restricted to spaces of paths defined by a finite number of their values. And it has computational power, as we shall see shortly. It is defined as follows.

Let $\mathcal{F}(\Omega)$ be the set of closed subspaces $V, W, \ldots$ of Ω of finite codimension partially ordered by the inclusion relation. The space V belongs to $\mathcal{F}(\Omega)$ if and only if it consists of points $\omega \in \Omega$ such that

$$\langle \omega'_j, \omega \rangle = 0 \qquad \text{for a finite set} \qquad V_0 \stackrel{\text{def}}{=} \{\omega'_j\} \ , \tag{I.A–5}$$

where $\omega'_j \in \Omega'$, the topological dual of Ω. If $V_0 \subset W_0$, then $W \subset V$.

Let Ω/V be the space of equivalence classes $[\omega]$ defined by the equivalence $\omega_1 \sim \omega_2 \langle = \rangle (\omega_1 - \omega_2) \in V$. Let P_V be the canonical mapping from Ω into Ω/V. Let $W \subset V$ and let P_{VW} be defined by

$$P_V = P_{VW} \circ P_W \ . \tag{I.A–6}$$

The quotient spaces $\Omega/V, \Omega/W, \ldots$ together with the canonical mappings P_{VW} : $\Omega/W \to \Omega/V \cdots$ form the projective system of finite-dimensional quotient spaces of Ω indexed by $\mathcal{F}(\Omega)$.

Example: For instance, let Ω be the space of continuous paths ω with fixed origin,

$$x(t, \omega) = \omega(t) \ , \quad \omega(t_0) = 0, \qquad t \in T \ .$$

The topological dual Ω' is the space of bounded measures. The duality in Ω is

$$\langle \omega', \omega \rangle \ = \int_T \omega(t)\, d\omega'(t) \tag{I.A–7a}$$

or

$$\langle \omega', \omega \rangle \ = \int_T \omega^\alpha(t)\, d\omega'_\alpha(t) \tag{I.A–7b}$$

or

$$\langle \delta'_t, \omega \rangle \ = \omega(t) \tag{I.A–7c}$$

as the case may be. Let θ_V be a partition of T

$$\theta_V = \{t_1, \ldots, t_V\}$$

and let $V_0 = \{\delta_{t_j}\}$ be indexed by θ_V. A path x belongs to V if $\langle \delta_{t_j}, x \rangle = x(t_j) = 0$. Two paths ω_1 and ω_2 are equivalent if

$$(\omega_1 - \omega_2)(t_j) = 0 \qquad \text{for every} \qquad t_j \in \theta_V \ .$$

A point $[\omega] \in \Omega/V$ is defined by its values $\omega(t_j)$ for every $t_j \in \Omega_V$. The canonical map

$$P_V : \Omega \to \Omega/V \ \text{ by } \ \omega \mapsto [\omega] = \{u^1, \ldots, u^V\} \ \text{ with } \ u^j = \langle \delta_{t_j}, \omega \rangle \ . \tag{I.A–8}$$

If we choose V_0 to be a set of Dirac distributions $\{\delta_{t_j}\}$, we replace a path by a finite set of its values. How to choose V_0 depends on the path integral to be computed.

So much for the projective family $\mathcal{Q}$ of finite-dimensional spaces related to Ω. We can now define a promeasure. A promeasure $\mu_{\mathcal{Q}}$ is a family of bounded measures $\{\mu_V\}$ on $\{\Omega/V\}$ such that

$$\begin{cases} \mu_V(\Omega/V) \text{ is independent of } V; \\ \text{when } W \subset V, \ \mu_V \text{ is the image of } \mu_W \text{ under } P_{VW} \ . \end{cases} \tag{I.A–9}$$

It is an easy matter, and it will be profitable, to restate the coherence conditions satisfied by the family $\mu_{\mathcal{Q}}$ of bounded measures as coherence conditions satisfied by the family $\mathcal{F}\mu_{\mathcal{Q}}$ of their Fourier transforms. The Fourier transform of a measure μ_V on Ω/V is defined on the dual of Ω/V. The space Ω/V is finite-dimensional (in the previous example, $[\omega] = \{u^1, \ldots, u^V\} \equiv u$). The dual $(\Omega/V)'$ is also finite-dimensional, of the same dimension as Ω/V. We shall label its points $[\omega]'$ or u'. The Fourier transform of μ_V is, by definition,

$$\mathcal{F}\mu_V([\omega]') = \int_{\Omega/V} \exp\left(-i\langle [\omega]', [\omega] \rangle\right) d\mu_V([\omega]) \ . \tag{I.A–10}$$

We introduce the transposed mapping $\tilde{P}_V : (\Omega/V)' \to \Omega'$ in order to go back to our aim, which is to define objects on the infinite-dimensional space Ω.

The transposed mapping $\tilde{P}_V$ of the linear continuous mapping P_V is by definition

$$\langle u', P_V\, \omega \rangle_{\Omega/V} = \langle \tilde{P}_V\, u', \omega \rangle_{\Omega} \qquad \text{for} \qquad \omega \in \Omega \ , \tag{I.A–11}$$

where $\langle \ , \ \rangle_{\Omega/V}$ is the duality in Ω/V and $\langle \ , \ \rangle_{\Omega}$ is the duality in Ω. If one labels $[\omega]'$ a point in $(\Omega/V)'$, then

$$\tilde{P}_V([\omega]') = \omega' \ .$$

Figure 1. P_V is a linear continuous mapping, $\tilde{P}_V$ its transposed. μ_Q is a promeasure on Ω defined as a family of measures μ_V on Ω/V for all $V \in \mathcal{F}(\Omega)$. The Fourier transform $\mathcal{F}\mu_V = \mathcal{F}\mu_Q \circ \tilde{P}_V$.

Note that there is no canonical isomorphism between either of these spaces and its duals, so that the label u' $[\text{resp}\,[\omega]']$ bears no relationship with u $[\text{resp}\,[\omega]]$. Thus, it is often better to write $\tilde{P}_V(u') = \omega'$ than the previous equation.

Let $\omega' = \tilde{P}_V\, u'$, the Fourier transform of the family μ evaluated at ω' is

$$\mathcal{F}\mu_{\mathcal{Q}}(\omega') = \mathcal{F}\mu_V(u') = \int_{\Omega/V} \exp(-i\langle u', u\rangle)\, d\mu_V(u) \ . \tag{I.A–12}$$

Since Ω' is the union of all V_0 for all $V \in \mathcal{F}(\Omega)$, equation (I.A–12) defines $\mathcal{F}\mu_{\mathcal{Q}}$ on Ω'.

The coherence conditions satisfied by $\mathcal{F}\mu_{\mathcal{Q}}$ are

$$\begin{cases} \mathcal{F}\mu_V(0) \text{ is independent of } V; \\ \text{when } W \subset V,\ \ \mathcal{F}\mu_V = \mathcal{F}\mu_W \circ \tilde{P}_{VW} \,. \end{cases} \tag{I.A–13}$$

We note that the coherence conditions (I.A–13) are simpler to implement than the coherence conditions (I.A–9) because they are not set statements.

Now, measures need not be defined as set functions; they can equivalently be defined as distributions of order zero. As set functions, the distinction between bounded and unbounded measures is formidable; as distributions, the distinction is interesting but not overwhelming. Given the facts that

$$\begin{cases} \text{(I.A–13) is easier to handle than (I.A–9), and} \\ \text{unbounded measures belong more naturally to distribution theory} \\ \text{than to set theory,} \end{cases}$$

I propose to work with the *pro*jective family $\mathcal{F}\mu_{\mathcal{Q}}$ of *distributions* $\{\mathcal{F}\mu_V; V \in \mathcal{F}(\Omega)\}$ satisfying the coherence conditions (I.A–13). Originally called "pseudomeasure," the family $\mathcal{F}\mu_{\mathcal{Q}}$ was shortly afterwards called "prodistribution" by Dieudonné. The Fourier transform $\mathcal{F}\mu_V$ is not restricted to being the Fourier transform of a bounded measure, thus prodistributions are generalizations of promeasures.

Important issues remained to be solved:

i) The space of test functions for $\mathcal{F}\mu_V$ is V-dependent. The set of all test functions for all $V \in \mathcal{F}(\Omega)$ is a difficult object to handle.

ii) The following theorem in the theory of promeasures has not been generalized to prodistributions:

"The mapping $\mu_{\mathcal{Q}} \to \mathcal{F}\mu_{\mathcal{Q}}$ of the set of promeasures on Ω to the set of functions on Ω' is injective."

However, it is possible to bypass these issues if one develops a theory of integration based on $\mathcal{F}\mu_{\mathcal{Q}}$ rather than on $\mu_{\mathcal{Q}}$. This theory is still rudimentary compared to the Lebesgue theory of integration but sufficient to compute many nontrivial physics problems.

Let $F = f \circ P_V$ for $V \in \mathcal{F}(\Omega)$ and $f \in \mathcal{S}(\Omega/V)$ where $\mathcal{S}$ is the Schwartz space whose dual is the space of tempered distributions. Then we can define

$$\int_{\Omega} F(\omega)\, d\mu_{\mathcal{Q}}(\omega) \text{ to be the number equal to } \int_{\Omega/V} f(u)\, d\mu_V(u) \ . \tag{I.A–14}$$

with

$$\mathcal{F}\mu_V = \mathcal{F}\mu_Q \circ \tilde{P}_V \ . \tag{I.A–15}$$

This definition has computing power.

Exercise: Compute the transposed $\tilde{P}_V$ of P_V defined by (I.A–8). Answer: $\tilde{P}_V$ is defined by (I.A–11), which here reads

$$\langle u', u\rangle_{\Omega/V} = \sum_i u'_i u^i = \sum_i u'_i \langle \delta_{t_i}, \omega\rangle = \langle \sum_i u'_i \delta_{t_i}, \omega\rangle = \langle \tilde{P}_V u', \omega\rangle_\Omega \ .$$

Hence,

$$\tilde{P}_V u' = \sum_i u'_i \delta_{t_i} \ . \tag{I.A–16}$$

It is easy to give an intuitive presentation of prodistributions when μ is a gaussian integrator. Let μ be a gaussian integrator on $\mathbb{R}^n$,

$$d\mu_s(x) = (2\pi s)^{-n/2} (\det A^{-1})^{1/2} \exp\left(-\tfrac{1}{2s}(A^{-1})_{ij}\, x^i x^j\right) dx^1 \ldots dx^n \tag{I.A–17}$$

where $s = 1$ for real gaussian (a bounded measure) and $s = i$ for a complex gaussian (an unbounded measure). Its Fourier transform

$$(\mathcal{F}\mu_s)(x') = \exp\left(-\tfrac{s}{2}\, A^{ij}\, x'_i\, x'_j\right) \tag{I.A–18}$$

is equally well behaved whether $s = 1$ or $s = i$. Moreover, one cannot write in a compact form a gaussian μ on Ω, whereas its Fourier transform is the obvious continuum limit of (I.A–18), namely,

$$(\mathcal{F}\mu_s)(\omega') = \exp\left(-\tfrac{s}{2}\int_T\int_T G(t,s)\, d\omega'(t)\, d\omega'(s)\right) \ . \tag{I.A–19}$$

The use of Fourier transforms in functional integration in field theory has long been proved useful. There it is written formally

$$\int \mathcal{D}\varphi \exp\left(i\, S(\varphi) + i\int_x \varphi(x)\, J(x)\, dx\right) \ . \tag{I.A–20}$$

This expression can be considered as the Fourier transform of the integrator $\mathcal{D}\varphi \exp\left(iS(\varphi)\right)$ evaluated at J.

B. Computing path integrals. $I = \int_\Omega F(\omega)\, d\mu(\omega)$.

1. Linear Methods. It often happens that F can be decomposed into two maps

$$F = f \circ P \tag{I.B–1}$$

where P is a continuous linear map from Ω into a linear space U,

$$P : \Omega \to U \text{ by } \omega \mapsto u$$

and f is an "arbitrary" map $f : U \to \mathbb{R}$. In this case we can immediately write down (see previous section)

$$I = \int_\Omega (f \circ P)(\omega)\, d\mu(\omega) = \int_U f(u)\, d(P\mu)(u) \tag{I.B–2}$$

where $P\mu$ is the image of μ under P and the Fourier transform of $P\mu$ is given in terms of the Fourier transform of μ by

$$\mathcal{F}(P\mu) = \mathcal{F}(\mu) \circ \tilde{P} \ . \tag{I.B–3}$$

Examples of linear mappings P on vector spaces of paths X. First, two examples of vector spaces of paths: the space of continuous paths, $x : T \to \mathbb{R}^n$, and the space of continuous paths x with vanishing boundary conditions.

i) $P : X \to y$ by $x \mapsto y$ such that $y(t) = \displaystyle\int_0^\infty K(t,s)\, x(s)\, ds$. (I.B–4)

$K(t,s)$ can be a matrix; it can also be proportional to a step function restricting the domain of integration.

ii) If the space X admits a denumerable basis $\{\Phi_k\}$ (e.g., in a Sturm-Liouville problem), the following map is often useful

$$P : X \to \mathbb{R}^\infty \text{ by } y_k = \int_T x(s)\, \Phi_k(s)\, ds \ . \tag{I.B–5}$$

This map is particularly useful whenever one encounters eigenvectors with vanishing eigenvalues.

iii) We can generalize to arbitrary elements of the dual X' of X the example (I.A–7, I.A–8)

$$P : X \to \mathbb{R}^p \text{ by } y^k = \langle \mu_k, x \rangle_X \text{ for } \mu_1, \ldots \mu_p \in X' \ . \tag{I.B–6}$$

Having used (I.B–2) the linear map P to rewrite the path integral, what next? It depends if P is of the type *i*), *ii*), or *iii*). It often happens that P is of type *iii*). The integrand, upon careful examination, is not a function of $x(\cdot, \omega)$ but a function of several $\langle \mu_k, x(\cdot, \omega) \rangle$, say p of them. Then the right-hand side of (I.B–2) is an integral over $\mathbb{R}^p$. If μ is a gaussian, $P\mu$ is a gaussian, and it is straightforward to write down explicitly the right-hand side of (I.B–2) given the left-hand side of (I.B–3). See (I.A–17) and (I.A–18). The work consists of inverting a $p \times p$ matrix and computing its determinant. If p is small—say less than 3, at most 4, as is often the case—then one does it. If p is large, for instance, the path has been discretized and $\{\mu_k\}$ is the family $\{\delta_{t_k}\}$ for a large number of t_k, then usually the system is defined by an action; the matrix to be inverted comes from the second variation of the action; and the calculus of variation gives techniques fully worked out to invert the matrix of interest (DeWitt-Morette, 1976; DeWitt-Morette, 1984).

If P is of type *ii*) with $\{\Phi_k\}$ a complete set of eigenfunctions of a Sturm-Liouville problem, then usually most of the y_k defined by (I.B–5) can be trivially integrated, leaving a few y_k physically important. The integral over $\mathbb{R}^\infty$ is a trivial integral over a space of finite codimension, say p, and a nontrivial integral over $\mathbb{R}^p$.

If P is of type *i*), there often exists another linear map from Y into $\mathbb{R}^\infty$ or $\mathbb{R}^p$ of type *ii*) and *iii*).

If none of the above is true, one can resort, if justified, to an expansion of $F = \sum_k f_k \circ P_k$.

The linear methods are particularly useful when the integrator is gaussian. This does not imply that we then integrate gaussians because in (I.B–1) the mapping f is "*arbitrary*." When the system is defined by an action, the best gaussian to choose is the gaussian whose Fourier transform is

$$(\mathcal{F}\mu)(\omega') = \int_T d\omega'_\alpha(t) \int_T d\omega'_\beta(s)\, G^{\alpha\beta}(t,s) \tag{I.B–7}$$

where $G^{\alpha\beta}(t,s)$ is the Green function of the Jacobi operator obtained from the second (functional) derivative of the action. Its boundary conditions are determined by the space of paths over which one integrates. For instance, consider the space of paths $x : [t_a, t_b] \times \Omega \to \mathbb{R}^n$ with $x(t_a,\omega) = a$, $x(t_b,\omega) = b$. Since Ω must be a vector space, we can only integrate over paths with vanishing boundary conditions: set[2]

$$x = q + \eta \tag{I.B–8}$$

where $q(t_a) = a$, $q(t_b) = b$, and make a change of variable of integration so that the new variable of integration is η, which indeed has vanishing boundary conditions. Since

$$\int_\Omega \eta^\alpha(t,\omega)\, \eta^\beta(s,\omega)\, d\mu(\omega) = G^{\alpha\beta}(t,s) \ , \tag{I.B–9}$$

$G^{\alpha\beta}(t,s)$ inherits the boundary conditions of η.

The interesting fact is that one does not *choose* this gaussian; one derives it from the Feynman-Kac's formula (I.B–20a) by appropriate linear mappings (DeWitt-Morette et al., 1979).

2. Stochastic Methods. These linear procedures have been used extensively in a great variety of situations. See DeWitt-Morette (1987) for references. But if nonlinear procedures are needed, we can turn to stochastic calculus for suggestions, possibly using Fourier transforms as a bridge to transfer techniques. But first a word of caution.

In addition to the profound difference between bounded and unbounded measures, there are two other easy-to-handle but noteworthy differences between Wiener and Feynman integrals.

---

[2] If $x(t,\omega)$ does not belong to $\mathbb{R}^n$, consider all the one-parameter families of paths around q and integrate over the vector fields along q defined by these families (see DeWitt-Morette et al., 1979).

i) In a Wiener integral a path has dimention $T^{1/2}$, e.g.,

$$\int_\Omega d\mu(\omega)\left(x(t,\omega)-x(t_0,\omega)\right)^2 = t - t_0 \ . \tag{I.B–10}$$

In a Feynman integral a path has dimension L, e.g., in a WKB approximation, one writes

$$x(t,\omega) = q(t) + \eta(t,\omega) \tag{I.B–11}$$

where $q(t)$ is the classical path. We shall label z the Brownian path satisfying (I.B–10), and the corresponding path in Feynman integral will be

$$x = \mu z \tag{I.B–12}$$

where μ is a constant of dimension $LT^{-1/2}$, e.g., $\mu = \sqrt{\hbar/m}$. Then if in (I.B–11) we wish to use a variable of integration ξ with the dimension of a Brownian path, we write

$$x = q + \mu\xi \ ; \tag{I.B–13}$$

and semiclassical expansions are naturally cast as expansions in powers of $\mu = \sqrt{\hbar/m}$.

ii) In a diffusion equation one models systems such as the following. Some matter, concentrated at x_0 at time t_0, diffuses randomly. One gives a probability distribution of the matter at time t by means of a random variable, defined on a probability space $(\Omega, \mathcal{F}, \mu)$

$$x(t,\cdot) : \Omega \to \mathbb{R}^n \ , \quad \text{or} \quad x(t) : \Omega \to \mathbb{R}^n \ . \tag{I.B–14}$$

Often, but not necessarily, $x(t)$ is defined by a stochastic differential equation defined by a Brownian path $z(t)$ in $\mathbb{R}^m$

$$dx(t) = X\big(x(t)\big)\,dz(t) + A\big(x(t)\big)\,dt \ , \qquad x(t_0,\omega) = x_0 \tag{I.B–15}$$

where

$$\begin{aligned} X\big(x(t)\big) &: \mathbb{R}^m \to \mathbb{R}^n \ , \quad \text{i.e., } X : \mathbb{R}^n \to L(\mathbb{R}^m, \mathbb{R}^n) \ , \\ A\big(x(t)\big) &: \mathbb{R} \ \to \mathbb{R}^n \ , \quad \text{i.e., } A : \mathbb{R}^n \to L(\mathbb{R}\ , \mathbb{R}^n) \ , \end{aligned}$$

are given "arbitrary" maps. One is usually interested in a function φ of the diffused matter. One knows $\varphi\big(x(t,\omega)\big)$ only probabilistically. A quantity of interest is its average Ψ over the whole diffused matter. The average Ψ is the function of the starting point x_0 and the time t when one looks at the diffusing matter

$$\Psi(x_0,t) = \int_\Omega d\mu(\omega)\,\varphi\big(x(t,\omega)\big) \ . \tag{I.B–16}$$

The path integral (I.B–16) satisfies the following diffusion equation

$$\frac{\partial \Psi}{\partial t} = \frac{1}{2} \sum_{i} X_i^{\alpha}(x_0)\, X_i^{\beta}(x_0)\, \frac{\partial^2 \Psi}{\partial x_0^{\alpha}\, \partial x_0^{\beta}} + A^{\alpha}(x_0)\, \frac{\partial \Psi}{\partial x_0^{\alpha}} \tag{I.B–17a}$$

$$\Psi(x_0, t_0) = \varphi(x_0) \ . \tag{I.B–17b}$$

The path integral solution $\Psi(x,t)$ of a Schrödinger equation is evaluated at the final position x of the paths: we integrate over all the paths that end at x at time t. We can map the space Ω_0 of paths on $T = [t_0, t]$ such that $x(t_0) = 0$ into the space of paths Ω_t such that $x(t) = 0$ by reparametrizing the paths in Ω_0. To $\tilde{x} \in \Omega_0$ we associate $x \in \Omega_t$ by

$$x(s) = \tilde{x}(t + t_0 - s) \ . \tag{I.B–18}$$

If $\tilde{x}$ is differentiable, then $dx(s)/ds = -d\tilde{x}(t + t_0 - s)/dt$. For more details, see DeWitt-Morette and Elworthy (1978).

It is, however, in some respects more intuitive to work with path integral solutions of diffusion equations than with path integral solutions of Schrödinger equations: We know if a Brownian path has started at 0; we do not know ahead of time if it will end at 0. On the other hand, $\Psi(x,t) = \int_{\Omega_t} d\mu(\omega)\, \varphi\big(x(t_0,\omega)\big)$, and it is more intuitive to work with the initial wave function φ evaluated at $x(t_0,\omega)$ rather than at $x(t,\omega)$ as in (I.B–16). See Section III.B.2 for the difference.

For the sake of brevity, I shall present the stochastic techniques in their usual setting; to obtain (formally) the corresponding results in quantum mechanics, one has to make sure that:

i) in the path integral $\int_{\Omega} F(\omega)\, d\mu(\omega)$, Ω is a vector space, μ a prodistribution;
ii) the paths are scaled to be of dimension L (I.B–12);
iii) the paths are run "backwards" (I.B–18).

One can look at the path integral (I.B–16)

$$\Psi(x_0, t) = \int_{\Omega} d\mu(\omega)\, \varphi\big(x(t,\omega)\big)$$

from different points of view; this is the very reason a path integral is a versatile tool, and many techniques can be brought to bear on its computation or its approximations or in obtaining information without computing it.

Let us look at a slightly richer system than the one presented in equations (I.B–14) to (I.B–17). Consider the system of stochastic differential equations

$$\begin{cases} dx(t) = X\big(x(t)\big)\, dz(t) \ , \quad x(t_0) = x_0 \in \mathbb{R}^n \\ dv(t) = V\big(x(t)\big)\, v(t)\, dt \ , \ v(t_0) = 1 \, ; \text{ i.e., } v(t) = \exp \displaystyle\int_{t_0}^{t} V\big(x(s)\big)\, ds \, , \end{cases} \tag{I.B–19}$$

with X and V given, "arbitrary." The effect of including a term $A(x(t))\,dt$ in the first equation can be read off equation (I.B–17) and need not be included for the purpose of the present discussion. Consider the path integral

$$\begin{aligned}\Psi(x_0,t) &:= \int_\Omega \varphi\big(x(t,\omega)\big)\, v(t,\omega)\, d\mu(\omega) \\ &\equiv \int_\Omega \varphi\big(x(t)\big) \exp\Big(\int_{t_0}^t V\big(x(s)\big)\, ds\Big)\, d\mu(\omega)\ ,\end{aligned} \tag{I.B–20a}$$

also written by probabilists

$$\Psi(x_0,t) := \mathbb{E}\Big(\varphi\big(x(t)\big)\, v(t)\Big)\ , \tag{I.B–20b}$$

also written by analysts

$$\Psi(x_0,t) := (P_{t_0}^t \varphi)(x_0)\ , \tag{I.B–20c}$$

also written by geometers

$$\Psi(x_0,t) := \mathbb{E}\,\varphi\big(F_{t_0}(x_0,t)\big)\ , \qquad \text{where} \quad x(t,\cdot) = F_{t_0}(x_0,t,\cdot)\ . \tag{I.B–20d}$$

It can be shown by various methods that

$$\begin{cases} \dfrac{\partial \Psi}{\partial t} = \dfrac{1}{2}\displaystyle\sum_\imath X_\imath^\alpha(x_0)\, X_\imath^\beta(x_0) \dfrac{\partial^2 \Psi}{\partial x_0^\alpha\, \partial x_0^\beta} + V(x_0)\Psi \equiv \mathcal{A}(x_0)\Psi\ , \\ \Psi(x_0,t_0) = \varphi(x_0)\ . \end{cases} \tag{I.B–21}$$

The different expressions (I.B–20) reflect the different points of view.

i) A physicist says, "The *path integral* (I.B–20a) solves the diffusion equation (I.B–21)," and he[3] computes the path integral by the classic methods: Feynman diagrams, semiclassical expansions, Monte Carlo numerics, or by the methods presented here (linear methods and, in Section III, stochastic methods). Ω and μ are spelled out to make use of equations such as (I.B–2).

ii) A probabilist says, "The *process* (I.B–19) solves the diffusion equation (I.B–21)," and he investigates various processes; he is usually more interested in the properties of the average (expectation value) (I.B–20b) than in its value, so that he works with a fixed probability space $(\Omega, \mathcal{F}, \mu)$ and does not spell it out in (I.B–20b).

iii) An analyst says, "The generator of the *semigroup* $\{P_s^t\}$ (I.B–20c) on the space of functions φ is the differential operator $\mathcal{A}$ (I.B–21). If φ is the characteristic function $\mathbb{1}_B$ of the set $B \subset \mathbb{R}^n$, then $P_s^t(\mathbb{1}_B)$ defines a transition probability $p(s,x_0;t,B)$, which solves various partial differential equations." He investigates the semigroups $\{P_s^t\}$ on various spaces of functions, e.g., L^∞ spaces or L^2 spaces.

iv) A geometer says, "$F_{t_0}(\cdot,t,\omega)$ (I.B–20d) is a *flow*, which maps $\mathbb{R}^n$ into $\mathbb{R}^n$." He investigates flows on manifolds other than $\mathbb{R}^n$.

[3] Read "he/she" where appropriate.

What do physicists learn by talking to their colleagues?

From a probabilist, a physicist learns that a change of variable of integration in (I.B–20a), say, from $x(t)$ given in Cartesian coordinates to $x(t)$ given in polar coordinates, is not done in stochastic calculus as in differential calculus because in the first case $(\Delta x)^2 \sim \Delta t$, whereas in the second case $\Delta x \sim \Delta t$. The correct change of variables in stochastic calculus introduces terms that have no counterpart in differential calculus. The complication can be removed by a path-dependent time reparametrization "adapted" to the change of coordinates. The final expression is totally different from the one obtained by change of coordinates in differential calculus, but it is far simpler than the result obtained without time reparametrization. For explicit calculations, see Young and DeWitt-Morette (1986).

From a geometer, a physicist learns to set up processes (I.B–20) on fibre bundles and to compute a path integral with integrands defined on the base space. This is obviously a suitable approach for quantum mechanics in curved spacetimes. We shall set up stochastic processes on a frame bundle over spacetime and consider quantities defined on the base space. But stochastic processes on fibre bundles do more than solving problems of quantum mechanics in curved spacetimes. They solve problems of quantum mecanics in the presence of gauge fields; they solve problems of quantum mechanics on multiply connected spaces; they solve problems whenever fibre bundles offer an appropriate description of the system under consideration.

The next chapter will be devoted to stochastic processes on fibre bundles and, in particular, to stochastic processes on frame bundles.

Stochastic processes on fibre bundles appear to be so useful that it is natural to present a quantization scheme (last lecture), which begins with a stochastic process on a fibre bundle (defined by the system under consideration); path integrals are defined by the stochastic process—they yield the Lagrangian and the Hamiltonian operator of the system. This procedure removes the ambiguities one encounters when one *begins* with the Lagrangian.

II. STOCHASTIC PROCESSES ON FIBRE BUNDLES

A. Differential Versions of Stochastic Processes on Fibre Bundles

1. Principal bundle. For concreteness we shall consider the frame bundle. We shall assume that the bundle has been trivialized and we shall work on one patch. Consider a path $q(t)$ on the base space, its horizontal lift $\rho(t)$ in the bundle, and the image $g(t)$ of the horizontal lift on the typical fibre $G = GL(n, \mathbb{R})$. Set $q(t_0) = q_0$, $\rho(t_0) = \rho_0$, $g(t_0) = g_0$. The horizontal lift is defined by a connection σ

$$\frac{d\rho(t)}{dt} = \sigma\big(\rho(t)\big)\,\frac{dq(t)}{dt} \quad . \tag{II.A–1}$$

We cannot construct a stochastic version "$d\rho(t) = \sigma\big(\rho(t)\big)\,dz(t)$" of this equation because a Brownian path $z(t) \in \mathbb{R}^n$ while $dq(t)/dt \in T_{q(t)}M^n$. (Note the t-dependence of this space.) However, we can use the fact that a frame

$$\rho(t) : \mathbb{R}^n \to T_{q(t)}M^n \ , \quad \text{hence } \big(\rho(t)\big)^{-1} : T_{q(t)}M^n \to \mathbb{R}^n$$

Figure 2. A frame bundle with structure group G.

to rewrite (II.A–1) in a form suitable for our purpose:

$$\frac{d\rho(t)}{dt} = \Big(\sigma\big(\rho(t)\big) \circ \rho(t)\Big) \left(\big(\rho(t)\big)^{-1} \frac{dq(t)}{dt}\right) . \tag{II.A–2a}$$

The soldering form $\big(\rho(t)\big)^{-1}(dq(t)/dt) \in \mathbb{R}^n$, and anticipating further development we call it $(dz(t)/dt)$. Set $X\big(\rho(t)\big) := \sigma\big(\rho(t)\big) \circ \rho(t)$, then[4]

$$\frac{d\rho(t)}{dt} = X\big(\rho(t)\big) \frac{dz(t)}{dt} \tag{II.A–2b}$$

has a stochastic version

$$d\rho(t) = X\big(\rho(t)\big)\, dz(t) \ . \tag{II.A–3}$$

Exercise: Properties of (II.A–2b). Set $x(t) = \big(\rho(t), q(t)\big)$ a path in the frame bundle; *i*) show that if (in (II.A–2b)) $dz(t)/dt$ is constant, then $q(t)$ is a geodesic; *ii*) show that (II.A–2b) implies that $q(t)$ is the Cartan development of $z(t)$.

i) $dz/dt = c$ implies $\rho^{-1}\, dq/dt = c$; i.e., the components of the tangent vector to q remain constant in the frame parallel transported along q. Hence, q is a geodesic. We can also check that the covariant derivative of dq/dt along $q(t)$ vanishes.

$$\frac{dq(t)}{dt} = \frac{d}{dt}\Big(\Pi\big(x(t)\big)\Big) \quad \text{where } x(t) = \big(\rho(t), q(t)\big) \ ,$$

but since here $\rho(t)$ is the horizontal lift of $q(t)$,

$$\begin{aligned} \frac{dq(t)}{dt} &= \Pi'\big(\dot\rho(t)\big) = \Pi'\Big(X\big(\rho(t)\big)\, \dot z(t)\Big) = \rho(t)\, \dot z(t) \\ \frac{D}{dt}\, \dot q(t) &= \rho(t) \frac{d}{dt}\, \big(\rho^{-1}(t)\, \dot q(t)\big) = \rho(t) \frac{d}{dt}\, c = 0 \ . \end{aligned} \tag{II.A–4}$$

[4] In principal bundles other than frame bundles (i.e., when there is no soldering form), one can use the other definition of connections; namely, a connection is a one-form on the tangent bundle of the principal bundle with values in the Lie algebra of the structure group. This definition provides the linear spaces needed to define Brownian paths.

ii) q is said to be the development of z if

$$\rho_0^{-1} \int_0^t \text{(parallel transp.)}^{-1}\, \dot{q}(s)\, ds = \int_0^t \dot{z}(s)\, ds \quad \text{for every } t \ , \qquad \text{(II.A–5)}$$

the parallel transport being from $q(s)$ to q_0 along q. The left-hand side of (II.A–5) is equal to

$$\begin{aligned} \rho_0^{-1} \int_0^t \rho_0\big(\rho(s)\big)^{-1} \dot{q}(s)\, ds &= \int_0^t \big(\rho(s)\big)^{-1}\, \Pi'\big(\dot{\rho}(s)\big)\, ds \\ &= \int_0^t \big(\rho(s)\big)^{-1}\, \Pi'\Big(X\big(\rho(s)\big)\, \dot{z}(s)\Big)\, ds \\ &= \int_0^t \big(\rho(s)\big)^{-1}\, \rho(s)\, \dot{z}(s)\, ds \ . \quad \blacksquare \end{aligned}$$

2. Associated vector bundle. Given a principal G-bundle, and a representation (ρ, F) of G on a vector space F, the parallel transport $v(t)$ of v_0 from q_0 to $q(t)$ is

$$v(t) = \rho\big(g(t)\, g_0^{-1}\big)\, v_0 \qquad \text{(II.A–6)}$$

where $g(t)$ is the image on the typical fibre G of the horizontal lift of $q(t)$. The connection stated in terms of σ in the previous example (II.A–1) can also be stated in terms of a form ω with values in the Lie algebra $\mathcal{L}(G)$. If we already know σ, then ω is the same connection as σ if

$$\omega \text{ (horizontal vector)} = 0 \ .$$

If we do not know σ, the choice of the connection ω determines the vertical component of a tangent vector to the bundle (hence indirectly its horizontal component) by

$$\omega(tg \text{ vector at } p) = \gamma \in \mathcal{L}(G) \Leftrightarrow \text{vertical component of the } tg \text{ vector at } p = \tilde{\gamma}(p)$$

where γ and $\tilde{\gamma}(p)$ are related by the canonical isomorphism between $\mathcal{L}(G)$ and the tangent space at p to the fibre at $\Pi(p)$. If $\gamma = dg(s)/ds|_{s=0}$ where $g(s)$ is a one-parameter subgroup, then

$$\tilde{\gamma}(p) = \frac{d}{ds}\big(\tilde{R}_{g(s)} p\big)\,|_{s=0} \qquad \text{(II.A–7)}$$

where $\tilde{R}_g$ is the right action of G on the bundle. Given the curve $g(t)$, in paragraph 1), image in G of the horizontal lift defined by σ, we shall now express it in terms of ω, the one form with values in $\mathcal{L}(G)$ that vanish on the horizontal vectors defined by σ.

Let $\phi : \Pi^{-1}\big(q(t)\big) = U \times G$ be a local trivialization such that (see caption of Fig. 4) for $x_0(t)$ defined by

$$\phi\big(x_0(t)\big) = \Big(\Pi\big(x_0(t)\big),\ \overset{\triangle}{\phi}\ \big(x_0(t)\big)\Big) = \big(q(t), e\big) \ .$$

Figure 3. On the left a principal bundle, on the right an associated vector bundle.

Then

$$\phi'_{x_0(t)} : T_{x_0(t)}\Big(\Pi^{-1}\big(q(t)\big)\Big) \to T_{q(t)}U \times T_eG$$

and

$$\phi'_{x_0(t)} \circ \sigma_{x_0(t)} = (id, \alpha) \ ;$$

where α is a one form on the base space with value in T_eG.

Let s be a section on the bundle such that

$$\phi \circ s : q(t) \mapsto \big(q(t), e\big) \ .$$

Then it can be proved (see, e.g., Choquet-Bruhat and DeWitt-Morette (1982), Part I, p. 367) that, for s^* the pull back mapping

$$\alpha = -s^*\omega \ .$$

If $x(t) = \tilde{R}_{g(t)}\, x_0(t)$, then $\sigma_{x(t)} = \tilde{R}'_{g(t)}\, \sigma_{x_0(t)}$ and

$$(\phi'_{x(t)} \circ \sigma_{x(t)})\Big(\frac{dq(t)}{dt}\Big) = \Big(\frac{dq(t)}{dt}\,,\ \frac{dg(t)}{dt}\Big)$$

with

$$\begin{aligned}\frac{dg(t)}{dt} &= R'_{g(t)}\,\alpha\Big(\frac{dq(t)}{dt}\Big) = -R'_{g(t)}\, s^*\omega\Big(\frac{dq(t)}{dt}\Big)\\ &= -s^*\omega\Big(\frac{dq(t)}{dt}\Big)\, g(t) \ .\end{aligned}$$

For example, the pull back $s^*\omega$ of a connection in a $U(1)$-bundle is the electromagnetic potential, or more precisely,

$$s^*\omega\Big(\frac{dq(t)}{dt}\Big) = i\,\frac{e}{\hbar c}\, A_\alpha\big(q(t)\big)\, \frac{dq^\alpha(t)}{dt} \in \mathcal{L}\big(U(1)\big) \ .$$

Then

$$dg(t) = -i\,\frac{e}{\hbar c}\,A_\alpha\big(q(t)\big)\,dq^\alpha(t)\,g(t)\ , \tag{II.A–8}$$

and since $U(1)$ is abelian,

$$g(t) = \exp\Big(-i\frac{e}{\hbar c}\int_0^t A_\alpha\big(q(t)\big)\,dq^\alpha(t)\Big)\ . \tag{II.A–9}$$

3. Weakly associated bundle. This bundle is not defined by a representation of the structure group of the principal bundle but by a representation of a group homomorphic to the structure group. For example, consider the wave function of a particle moving on a circle S^1. We are interested in the sum over all paths beginning at $q_0 \in S^1$ and ending at $q(t) \in S^1$. The space of paths on S^1 splits in an infinite number of homotopy classes labelled by the number $n \in \mathbb{Z}$ of loops a path has made in going from q_0 to $q(t)$. The universal covering of S^1 is $\mathbb{R}$.

A universal covering $\widetilde{M}$ of a manifold M is a simply connected covering of M. It is a principal bundle.

$$\Pi : \widetilde{M} \to M = \widetilde{M}/G \tag{II.A–10}$$

where G is the discrete group of automorphisms of M isomorphic to the fundamental group (first homotopy group) $\Pi_1(M)$. In the above example

$$S^1 = \mathbb{R}/\mathbb{Z}\ .$$

The universal covering has a unique connection: a horizontal lift $\tilde{q}$ of a path q in the base space is the unique lift in $\widetilde{M}$ with a given $\tilde{q}(t_0)$.

A scalar wave function over S^1 is a section of a vector bundle ξ with typical fibre $\mathbb{C}$; we are interested in the action of $U(1)$ on the wave function. Let

$$a : \mathbb{Z} \to U(1) \qquad \text{by} \qquad n \mapsto \exp in\alpha\ , \qquad \alpha \in \mathbb{R}\ . \tag{II.A–11}$$

Figure 4. s is the section defined by the trivialization, i.e., $s : q(t) \mapsto x_0(t)$ such that $\overset{\triangle}{\phi}\big(x_0(t)\big) = e \in G$. The mapping $s^*\big(x_0(t)\big) : T^*_{x_0(t)}\,\text{Bundle} \to T^*_{q(t)}\,\text{Base}$.

Let $\tilde{a}$: Prin $\mathbb{Z}$-bundle $\to$ Prin $U(1)$-bundle over S^1, i.e., $\tilde{a}$ maps the universal cover of S^1 into the principal bundle associated to the vector bundle ξ:

$$\tilde{a}\big(\tilde{q}(t)n\big) = \tilde{a}\big(\tilde{q}(t)\big)\, a(n) \ , \qquad n \in \mathbb{Z} \ .$$

The parallel transport of a wave function from $q(t)$ back to q_0 is

$$\tau_t^{t_0}\, \varphi\big(q(t)\big) = \tilde{a}\big(\tilde{q}(t_0)\big)\, \big[\tilde{a}\big(\tilde{q}(t)\big)\big]^{-1}\, \varphi\big(q(t)\big) \ , \tag{II.A–12a}$$

which is often abbreviated to

$$\tau_t^{t_0}\, \varphi\big(q(t)\big) = \tilde{q}(t_0)\, \big(\tilde{q}(t)\big)^{-1}\, \varphi\big(q(t)\big) \ , \tag{II.A–12b}$$

although, as it stands, this last equation is incorrect.

The space of paths Ω from $\tilde{q}(t_0)$, chosen abitrarily, to any point $\tilde{q}(t)$ covering $q(t)$ decomposes into subspaces characterized by the final point $\tilde{q}(t)$

$$\Omega = \bigcup_{\mathbb{Z}} \Omega^n$$

where $\tilde{q}_n \in \Omega^n$ means that $\tilde{q}_n(t) = \tilde{q}_n$ such that $\pi(\tilde{q}_n) = q(t)$. We have

$$\tilde{q}_k(t) = \tilde{q}_n(t)\, (n)^{-1}\, (k) \tag{II.A–13}$$

where (n) is the group action of $\mathbb{Z}$ on $\mathbb{R}$: $\tilde{q}_0(t)(k) = \tilde{q}_o(t) + 2\pi\, k\, \mathrm{Radius}$. The parallel transport (II.A–9) along a path q with lift $\tilde{q}_n$ is

$$\begin{aligned} \tau_t^{t_0}\, \varphi\big(q(t)\big) &= \tilde{a}\Big(\tilde{q}(t_0)\, \big(\tilde{q}_n(t)\big)^{-1}\Big)\, \varphi\big(q(t)\big) \\ &= \tilde{a}\Big(\tilde{q}(t_0)\, \big(\tilde{q}_0(t)\big)^{-1}\Big)\, \big(a(n)\big)^{-1}\, \varphi\big(q(t)\big) \\ &= \exp\left(-in\alpha\right) \tilde{q}(t_0)\, \big(\tilde{q}_0(t)\big)^{-1}\, \varphi\big(q(t)\big) \end{aligned} \tag{II.A–14}$$

in abbreviated form.

Figure 5. A circle and its universal cover.

There are simpler ways (Laidlaw and DeWitt-Morette, 1971) to establish this result; but I wanted to present the variety of problems that can be solved by stochastic processes on fibre bundles. In general, the propagator on a multiply connected space M is a linear combination of the propagators; each propagator is obtained by summing over paths in the same homotopy class; the coefficients of the linear combinations form a unitary representation of the fundamental group of M. The propagator is defined modulo on overall phase factor.

B. Stochastic differential equations on fibre bundles

We have written down three candidates for stochastic differential equations that may lead to interesting diffusion manifolds.

a) On the frame bundle, the stochastic system[5] (II.A–3)

$$\begin{cases} dx(t) = X\big(x(t)\big)\, dz(t)\,, \text{ where } x(t) = \big(q(t), \rho(t)\big)\,, & x(t_0) = x_0\,, \\ dv(t) = V\Big(\Pi\big(x(t)\big)\Big)\, v(t)\, dt\ , & v(t_0) = 1\,, \end{cases} \tag{II.B–1}$$

defining a path integral over paths taking their values in a Riemannian manifold:

$$\Psi(q_0, t) = \int_\Omega \varphi\Big(\Pi\big(x(t,\omega)\big)\, v(t,\omega)\, d\mu(\omega)\ , \qquad \varphi : M \to \mathbb{R}\ . \tag{II.B–2}$$

b) On a vector bundle associated with a $U(1)$ bundle over $\mathbb{R}^n$, the stochastic equation (II.A–8) with $dq(t) = \mu\, dz(t) \in \mathbb{R}^n$,

$$dg(t) = -i\,\frac{e}{\hbar c}\, A_\alpha\big(q(t)\big)\, dq^\alpha(t)\, g(t)\ , \qquad g(t_0) = g_0\ , \tag{II.B–3}$$

defining a path of a particle in an electromagnetic field

$$\begin{aligned} \Psi(q_0, t) &= \int \varphi\big(q(t,\omega)\big)\, \big(g(t,\omega)\big)^{-1}\, d\mu(\omega) \\ &= \int_\Omega \varphi\big(q(t,\omega)\big) \exp\Big(i \int_0^t \frac{e}{\hbar c}\, A_\alpha\big(q(t,\omega)\big)\, dq^\alpha(t,\omega)\Big)\, d\mu(\omega)\ . \end{aligned} \tag{II.B–4}$$

c) On a vector bundle weakly associated to a universal covering, the stochastic equation obtained from (II.A–13) when $q(t)$ is a stochastic process

$$\tilde{q}_{g_1}(t) = \tilde{q}_{g_2}(t)\, g_2^{-1}\, g_1 \tag{II.B–5}$$

values in a multiply connected space:

$$\begin{aligned} \Psi(q_0, t) &= \sum_{g \in G} \int_{\Omega^g} \tilde{q}(t_0,\omega)\big(\tilde{q}_g(t,\omega)\big)^{-1} \varphi\big(q(t,\omega)\big)\, d\mu(\omega)\,, \quad \Omega = U\Omega^g \\ &= \sum_{g \in G} a(g^{-1}) \int_{\Omega^e} \tilde{q}(t_0,\omega)\, \big(\tilde{q}_e(t,\omega)\big)^{-1} \varphi\big(q(t,\omega)\big)\, d\mu(\omega)\ . \end{aligned} \tag{II.B–6}$$

---

[5] In order not to clutter the equations, we have abbreviated $\overset{\triangle}{\phi}\big(x(t)\big)$ to $x(t)$. Recall that $\overset{\triangle}{\phi}\big(x(t)\big) = \rho(t)$.

So far we have worked on one patch U assumed trivialized $\Pi^{-1}(U) = U \times G$ (principal bundle) or $\Pi^{-1}(U) = U \times F$ (associated bundle). We now have to face changes of coordinates on the overlap of two patches. A stochastic differential equation is in fact an integral, e.g.,

$$d\rho(t) = X\big(\rho(t)\big)\, dz(t), \rho(t_0) = \rho_0 \Leftrightarrow \rho(t) = \rho_0 + \int_{t_0}^{t} X\big(\rho(s)\big)\, dz(s) \ .$$

The integral, as it stands, is meaningless because $z(t)$ is not of bounded variation—intuitively, $dz(t) \simeq \sqrt{dt}$, then $\int_{t_0}^{t} (X \frac{dz}{dt})\, dt = \infty$ if defined as a Lebesque integral.

1. Stratonovich calculus. However, Itô and Stratonovich have proposed definitions of stochastic integrals that are the starting points of two very different stochastic calculi. We hope to decide whether to define the stochastic equations ((II.B–1), (II.B–3), (II.B–5)) by Itô integrals or Stratonovich integrals. The answer is "Stratonovich" because the Itô formula for change of variables is not tensorial. Indeed, an Itô integral is, by definition

$$\int X(t,\omega)\, dz(t,\omega) := \underset{\text{in measure}}{\text{limit}} \sum_j X(\tau_j,\omega)\big(z(t_{j+1},\omega) - z(t_j,\omega)\big) \qquad \text{(II.B–7)}$$

where $\tau_j \le t_j$. One says "the differentials stick out in the future," or "the integrand is nonanticipating." It follows from this definition that under a change of coordinates $\theta : \mathbb{R}^n \to \mathbb{R}^n$, the new coordinates $\theta\big(x(t)\big)$ are obtained from the old coordinates $x(t)$ by

$$\begin{aligned} \theta\big(x(t_b)\big) = \theta\big(x(t_a)\big) \ &+ \int_{t_a}^{t_b} D\theta\big(x(t)\big)\, dx(t) \\ &+ \frac{1}{2}\int_{t_a}^{t_b} D^2\theta\big(x(t)\big)\, dx(t)\, dx(t) \ . \end{aligned} \qquad \text{(II.B–8)}$$

The term

$$D^2\theta\, dx\, dx = \frac{\partial^2\theta}{\partial x^\alpha\, \partial x^\beta}\, dx^\alpha\, dx^\beta \qquad \text{(II.B–9)}$$

is not a tensor.

On the other hand, a Stratonovich integral is, by definition,

$$\begin{aligned} \int X(t,\omega)\, dz(t,\omega) \ := \underset{\text{in measure}}{\text{limit}} \sum_j \frac{1}{2}\big(X(t_{j+1},\omega) \\ + X(t_j,\omega)\big)\big(z(t_{j+1},\omega) - z(t_j,\omega)\big) \ . \end{aligned}$$

The mid-point rule suggests that Stratonovich change of variable of integration may be tensorial. Indeed, the mid-point rule applied to a Taylor expansion wipes out the second differentials

$$\begin{cases} \theta(b) - \theta(a) \ = \theta'(a)(b-a) + \frac{1}{2}\theta''(a)(b-a)^2 + 0\big((b-a)^3\big) \\ \theta(a) - \theta(b) \ = \theta'(b)(a-b) + \frac{1}{2}\theta''(b)(a-b)^2 + 0\big((b-a)^3\big) \end{cases}$$

gives

$$\theta(b) - \theta(a) = \tfrac{1}{2}\big(\theta'(a) + \theta'(b)\big)(b-a) + 0\big((b-a)^3\big) \ . \tag{II.B–10}$$

We shall prove that the Stratonovich integral is tensorial by using the Itô formula (II.B–8) and the relationship between Itô and Stratonovich integrals.

$$\text{Strat.} \int X\, dz = \text{Itô}\Big(\int X\, dz + \frac{1}{2}\int dX\, dz\Big) \ . \tag{II.B–11}$$

We have written the Itô and the Stratonovich integrals in terms of z, the letter we have used for Brownian paths. They are in fact more general. The question is, "What are the processes Z indexed by "time" for which $\int_0^t X_s\, dZ_s$ can be defined on a reasonably large class of integrands X in such a way that the Dominated Convergence Theorem holds?" (Bichteler, 1984). This is a task we shall be happy to let mathematicians do for us. But in order to be able to use their results, I shall use their notation

$$\text{Itô} \int_0^t X_s\, dZ_s \equiv \int_0^t X_s\, dZ_s \equiv (X * Z)_t \ . \tag{II.B–12}$$

Thus, $X * Z$ is thought of as a process indexed by "time." Similarly,

$$\text{Strat.} \int_0^t X_s\, dZ_s \equiv \int_0^t X_s\, \delta Z_s \equiv (X \bullet Z)_t \ . \tag{II.B–13}$$

With this notation, (II.B–11) is written

$$X \bullet Z = X * Z + \tfrac{1}{2}\langle X|Z\rangle \ . \tag{II.B–14}$$

The bracket $\langle X|Z\rangle$ can be defined by this equation given the definition of the Itô and Stratonovich integrals. Alternatively, (II.B–14) can be used to define Stratonovich integrals and the bracket defined by either of the following two equations

$$X_t^2 = X_0^2 + 2\int_0^t X\, dX + \langle X|X\rangle_t \tag{II.B–15}$$

obtained from Itô formula (II.B–8) with $\theta : X_t \to X_t^2$

$$X_t Y_t = X_0 Y_0 + \int_0^t X_s\, dY_s + \int_0^t Y_s\, dX_s + \langle X|Y\rangle_t \ . \tag{II.B–16}$$

In the following we consider only continuous integrators X, Y, Z. Since $\langle X|Z\rangle = \int dX_s\, dZ_s$, it vanishes if one of the integrators X or Z is of finite variation. As a process $\langle X|Z\rangle_t$ is of finite variation, hence

$$\begin{aligned} \langle X|Y \bullet Z\rangle = \langle X|Y * Z\rangle &= \int dX\, d\Big(\int Y\, dZ\Big) \\ &= \int Y\, dX\, dZ = Y * \langle X|Z\rangle \ . \end{aligned} \tag{II.B–17}$$

Exercise: Show by computing both sides of the equations that

$$X \bullet (Y \bullet Z) = (XY) \bullet Z \tag{II.B–18a}$$

$$X * (Y * Z) = (XY) * Z \ . \tag{II.B-18b}$$

Exercise: Show that

$$\langle \Phi_{,i}(X) | Y \rangle = \langle \Phi_{,ij}(X) * X^j | Y \rangle \ . \tag{II.B–19}$$

Answer: By Itô formula (II.B–8)

$$\Phi_{,i}(X) = \Phi_{,i}(X_0) + \Phi_{,ij}(X) * X^j + \tfrac{1}{2} \Phi_{,ijk}(X) * \langle X^j | X^k \rangle \ , \tag{II.B–20}$$

and since $\langle X^j | X^k \rangle$ is of finite variation, equation (II.B–19) follows.

Theorem: *Stratonovich stochastic differential equations transform like ordinary differential equations.*

Proof: Let $\Phi : U \to \mathbb{R}^n$ be a twice-differentiable map defined on an open subset $U \subset \mathbb{R}^n$. The derivative map of Φ at x

$$D\Phi(x) : \mathbb{R}^n \to \mathbb{R}^n \ .$$

Let X be a continuous vector-valued integrator whose values lie in U at all times; then

$$\Phi(X_t) = \Phi(X_0) + \int_0^t D\Phi(X_s)\, \delta X_s \ , \qquad 0 \le t \le \infty \ . \tag{II.B-21}$$

Indeed,

$$\begin{aligned}
D\Phi(X) \bullet X &= \Phi_{,i}(X) \bullet X^i && \text{by definition} \\
&= \Phi_{,i}(X) * X^i + \tfrac{1}{2} \langle \Phi_{,i}(X) | X^i \rangle && \text{by (II.B–14)} \\
&= \Phi_{,i}(X) * X^i + \tfrac{1}{2} \langle \Phi_{,ij}(X) * X^j | X^i \rangle && \text{by (II.B–19)} \\
&= \Phi_{,i}(X) * X^i + \tfrac{1}{2} \Phi_{,ij} * \langle X^j | X^i \rangle && \text{by (II.B–17)} \\
&= \Phi(X) - \Phi(X_0) && \text{by (II.B–8)} \ .
\end{aligned}$$

Suppose X solves the stochastic differential equation

$$X = x + A_\alpha(X) \bullet Z^\alpha \ . \tag{II.B–22}$$

It follows from (II.B–21) that

$$\begin{aligned}
\Phi(X) &= \Phi(x) + D\Phi(X) \bullet X = \Phi(x) + D\Phi(X) \bullet \big(A_\alpha(X) \bullet Z^\alpha \big) \\
&= \Phi(x) + D\Phi(X)\, A_\alpha(X) \bullet Z^\alpha \qquad \text{by (II.B–18)} \ .
\end{aligned}$$

Set $Y = \Phi(X)$ and $y = \Phi(x)$, then Y solves

$$Y = y + B_\alpha(Y) \bullet Z^\alpha \ , \tag{II.B–23}$$

where $B_\alpha = D\Phi\, A_\alpha \circ \Phi^{-1}$ is the image of A_α under the derivative map $D\Phi$: Equation (II.B–22) transforms as in ordinary differential calculus. ∎

2. Path integrals defined by stochastic processes on fibre bundles. We shall assume that the stochastic processes (II.B–1) and (II.B–3) are defined by Stratonovich integrals and investigate the properties of the path integrals (II.B–2) and (II.B–4). In Section III we shall compute pathwise linear approximations and semiclassical approximations of the Feynman-Kac formula for quantum systems in curved Riemannian manifolds (II.B–2).

a) Given the process $x(t)$ defined by the Stratonovich integral (II.A–3)

$$\begin{cases} x_t &= x_0 + (X \bullet z)_t \ ; \quad \Pi\big(x(t)\big) = q(t) \\ v_t &= \exp \displaystyle\int_0^t V\Big(\Pi\big(x(s)\big)\Big)\, ds \ . \end{cases} \tag{II.B–24}$$

We shall show that the following path integral, to be understood as (II.B–2) although the ω are not explicitly written,

$$\Psi(q_0, t) := \int_\Omega \varphi\Big(\Pi\big(x(t)\big)\Big) \exp\Big(\int_0^t V\Big(\Pi\big(x(s)\big)\Big)\, ds\Big)\, d\mu(\omega) \tag{II.B–25}$$

is a solution of the diffusion equation

$$\begin{cases} \dfrac{\partial \Psi}{\partial t} &= \Big(\dfrac{1}{2}\Delta + V\Big)\Psi \ , \\ \Psi(q_0, 0) &= \varphi(q_0) \ , \end{cases} \tag{II.B–26}$$

where Δ is the Laplacian defined by the connection implied in the process x by (II.B–24). As in $\mathbb{R}^n$, the proof rests on the Itô formula (II.B–8) applied to the function φ of the process $\Pi \circ x$ (II.B–24); it is clear from the results derived on $\mathbb{R}^n$ (I.B–19) and (I.B–21) that it is sufficient to prove the result when $V = 0$. First we express the Stratonovich equation $x(t) = x_0 + (X \bullet z)_t$ in terms of an Itô equation:

$$x(t) = x_0 + (X * z)_t + \tfrac{1}{2}\langle X|z\rangle_t \ . \tag{II.B–27}$$

The Itô formula (II.B–8) gives

$$\begin{aligned} \varphi\Big(\Pi\big(x(t)\big)\Big) &= \varphi\Big(\Pi\big(x(0)\big)\Big) + \int_0^t D(\varphi \circ \Pi)\big(x(s)\big)\, dx(s) \\ &\qquad + \tfrac{1}{2}\int_0^t D^2(\varphi \circ \Pi)\big(x(s)\big)\, dx(s)\, dx(s) \qquad \text{(II.B–28)} \\ &\equiv \varphi(q_0) + \big(D(\varphi \circ \Pi) * x\big)_t + \tfrac{1}{2}\big(D^2(\varphi \circ \Pi) * \langle x|x\rangle\big)_t \ . \end{aligned}$$

The explicit calculation of this equation is obviously intricate and we shall break it up into two steps: *i)* we concentrate on the contribution of the Stratonovich correction term $\frac{1}{2}\langle X|z\rangle$ and *ii)* we concentrate on the properties of the process x.

i) Set $\varphi \circ \Pi = f$; then

$$\begin{aligned} f(x(t)) = f(x(0)) \; &+ \int_0^t Df(x(s))\Big(X(x(s))\,dz(s) \\ &\qquad + \tfrac{1}{2} DX(x(s))\,X(x(s))\,dz(s)\,dz(s)\Big) \qquad \text{(II.B–29)} \\ &+ \tfrac{1}{2}\int_0^t D^2 f(x(s))\,X(x(s))\,dz(s)\,X(x(s))\,dz(s)\ . \end{aligned}$$

The Stratonovich correction term $\frac{1}{2}\langle X|z\rangle_t$ modifies the first integral but not the second one in (II.B–29) because $\int dz\,dz\,dz = 0$—alternatively because of (II.B–19). The integrals with respect to $dz\,dz$ can be combined:

$$\begin{aligned} &Df(x(s))DX(x(s))X(x(s))\,dz(s)\,dz(s) + D^2 f(x(s))\,X(x(s))\,dz(s)\,X(x(s))\,dz(s) \\ &\quad = \partial_i f(\partial_j X^i_k) X^j_l\,dz^l\,dz^k + (\partial_i\partial_j f) X^i_k\,dz^k\,X^j_m\,dz^m \\ &\quad = \sum_k \partial_i f(\partial_j X^i_k) X^j_k\,ds + \sum_k (\partial_i\partial_j f) X^i_k X^j_k\,ds \\ &\quad = \sum_k \partial_j(\partial_i f X^i_k) X^j_k\,ds = \sum_k X_k(X_k(f))\,ds \equiv \mathcal{L}^2_X(f)\,ds\,. \qquad \text{(II.B–30)} \end{aligned}$$

Hence, (II.B–29) has been simplified to read

$$\begin{aligned} f(x(t)) = f(x(0)) \; &+ \int_0^t X\Big(f(x(s))\Big)\,dz(s) \\ &+ \tfrac{1}{2}\int_0^t \mathcal{L}^2_X f(x(s))\,ds\ . \end{aligned} \qquad \text{(II.B–31)}$$

ii) Let $S(t, x_0)e$ be a solution of

$$dx(t) = X(x(t))e\,dt\ , \qquad \text{where } e \in \mathbb{R}^n\ . \qquad \text{(II.B–32)}$$

We have established (II.A–4) that $\Pi(x(t))$ is a geodesic at q_0; the components of its tangent are equal to e in the ρ_0 frame. Hence, $x(t)$ is the horizontal lift of a geodesic, at x_0 at $t = 0$. Then (II.B–31) can be rewritten

$$\begin{aligned} f(x(t)) = f(x(0)) \; &+ \int_0^t \frac{d}{dr} f \circ S(r, x(s))\Big|_{r=0} dz(s) \\ &+ \frac{1}{2}\int_0^t \frac{d^2}{dr^2} f \circ S(r, x(s))e\Big|_{r=0} (dz(s), dz(s))\ . \end{aligned} \qquad \text{(II.B–33)}$$

To prove that this equation is the same as (II.B–31) with $dS(t)/dt = X\big(S(t)\big)$, one computes explicitly the integrands: Equation (II.B–32) says

$$\left\{\begin{aligned} \frac{d}{dt}\Big(S\big(t,x(s)\big)e\Big) &= X\Big(S\big(t,x(s)\big)e\Big)e \ , \qquad e\in\mathbb{R}^n \\ S\big(0,x(s)\big)e &= x(s) \ . \end{aligned}\right. \tag{II.B–34}$$

$$\begin{aligned} \frac{d}{dr}\, f\circ S\big(r,x(s)\big)e &= Df\,\frac{d}{dr}\,S\big(r,x(s)\big)e = Df\,X\Big(S\big(r,x(s)\big)e\Big)e \\ \frac{d}{dr}\, f\circ S\big(r,x(s)\big)e\Big|_{r=0} &= Df\,X\big(x(s)\big)e \ . \end{aligned} \tag{II.B–35}$$

$$\begin{aligned} \frac{d^2}{dr^2}\, f\circ S\big(r,x(s)\big)e &= \frac{d}{dr}\,Df\,X\Big(S\big(r,x(s)\big)e\Big)e \\ &= D^2f\,X\Big(S\big(r,x(s)\big)e\Big)e\,X\Big(S\big(r,x(s)\big)e\Big)e \\ &\qquad + Df\,DX\Big(S\big(r,x(s)\big)e\Big)e\,X\Big(S\big(r,x(s)\big)e\Big)e \\ \frac{d^2}{dr^2}\, f\circ S\big(r,x(s)\big)e\Big|_{r=0} &= D^2f\,X\big(x(s)\big)e\,X\big(x(s)\big)e \\ &\qquad + Df\,DX\big(x(s)\big)e\,X\big(x(s)\big)e \ . \end{aligned} \tag{II.B–36}$$

Since $e\,e(dz,dz) = e_k\,e_l(dz^k,dz^l) = ds$, the above quadratic form applied to the pair (dz,dz) is identical to (II.B–30). ∎

Finally, we can work out explicitly (II.B–28) using (II.B–33), (II.B–35) and (II.B–36) with $f = \varphi\circ\Pi$. We shall also use the fact that $S(r,x_0)e$ is the lift of a geodesic.

$$\gamma(r,x_0) = \Pi\circ S(r,x_0)\,e \ . \tag{II.B–37}$$

Then, D/dr being the covariant derivative and Δ the Laplacian defined by the connection σ,

$$\begin{aligned} \frac{d^2}{dr^2}\varphi\circ\gamma\big(r,x(s)\big)\Big|_{r=0} &= \frac{d}{dr}\Big(D\varphi\frac{d\gamma}{dr}\big(r,x(s)\big)\Big)\Big|_{r=0} \\ &= \frac{d}{dr}\Big(\partial_k\varphi\frac{d\gamma^k}{dr}\big(r,x(s)\big)\Big)\Big|_{r=0} \\ &= \Big(\frac{D}{dr}D\varphi\Big)\frac{d\gamma}{dr}\big(r,x(s)\big)\Big|_{r=0} \\ &\qquad + D\varphi\frac{D}{dr}\frac{d}{dr}\gamma\big(r,x(s)\big)\Big|_{r=0} \\ &= \Delta\varphi\big(x(s)\big) \ ; \end{aligned} \tag{II.B–38}$$

the second term vanishes because γ is a geodesic.

Exercise: With the notation of Section II.A.2, use (II.B–36) and (II.B–30) to show that if the connection σ defining X (II.A–2b) is the Levi-Civita connection,

$$\Big(\overset{\triangle}{\phi}{}'_{x_0(t)}\circ\sigma_{x_0(t)}\Big)^k_{ij} = -(\Gamma_i)^k_j$$

with

$$\Gamma^k_{ij} = \tfrac{1}{2}\,g^{km}\left(\partial_i\,g_{jm} + \partial_j\,g_{im} - \partial_m\,g_{ij}\right) \ , \tag{II.B–39}$$

then

$$\Delta_x = g^{ij}\,\frac{\partial}{\partial x^i}\,\frac{\partial}{\partial x^j} - g^{ij}\,\Gamma^k_{ij}\,\frac{\partial}{\partial x^k}\ . \tag{II.B–40}$$

Hint: $\sum X^i_k\,X^j_k = g^{ij}$, $\quad \sum(\partial_j\,X^i_k)\,X^j_k = -g^{lm}\,\Gamma^i_{lm}$.

Remark: To obtain (II.B-26) one proceeds as usual. In brief, insert either (II.B-31) or (II.B-33) in the path integral and note that the martingale $\int \ldots dz$ does not contribute.

b) Given the process defined by the Stratonovich integral (II.B–3)

$$g(t) = \exp\left(-i\frac{e}{\hbar c}\,(A_\alpha \cdot q^\alpha)_t\right)\ , \qquad g(0) = 1\ , \tag{II.B–39}$$

we shall show that the following path integral, to be understood as (II.B–4) even though we do not explicitly write the ω,

$$\Psi(q_o, t) := \int_\Omega \varphi\big(q(t)\big)\exp\left(i\frac{e}{\hbar c}(A_\alpha \cdot q^\alpha)_t\right) d\mu(\omega)$$

is a solution of

$$\begin{cases} \dfrac{\partial\Psi}{\partial t} &= \dfrac{1}{2}\Big(D_\alpha + i\dfrac{e}{\hbar c}\,A_\alpha(x_0)\Big)^2\Psi \\ \Psi(q_0, 0) &= \varphi(q_0)\ . \end{cases}$$

$D_\alpha + i\frac{e}{\hbar c}A_\alpha(x)$ is the covariant derivative defined by the pull back of the connection on the base space $i\frac{e}{\hbar c}A_\alpha(x)$.

This is basically the same result as in the previous paragraph (II.B–26).

In conclusion, Stratonovich equations solve diffusion equations expressed in terms of covariant derivatives.

III. COMPUTING PATH INTEGRALS FOR SYSTEMS IN CURVED SPACETIMES

I shall present only computations based on stochastic processes on frame bundles—and only a few of them. Moreover, I shall present them briefly because they have already been published and because they are far too long to be reproduced here in full.

I want to write down approximations not only for the solution (II.B–25) but also for the solution of the Schrödinger equation.

$$\begin{cases} i\hbar\dfrac{\partial\psi}{\partial t} &= -\dfrac{\hbar^2}{2m}\,\Delta\psi + V\psi\ , \qquad t \in [t_a, t_b] \equiv T\ ; \\ \psi(a, t_a) &= \varphi(a)\ , \qquad a \in M\ . \end{cases} \tag{III.A–1}$$

The diffusion and the Schrödinger equations can both be written

$$\begin{cases} \dfrac{\partial\psi}{\partial t} &= \dfrac{1}{2}\mu^2 s\,\Delta\psi + \dfrac{1}{\mu^2 s}\,\dfrac{1}{m}\,V\psi \\ \psi(a,t_a) &= \varphi(a) \end{cases} \tag{III.A–2}$$

with ($\mu^2 = \hbar/m,\ s = i$) for the Schrödinger equations and ($\mu^2 = 1,\ s = 1$) for the diffusion equation. The path integral solution (II.B–25) of the diffusion equation $\Psi(a,t_b)$ is over the space Ω_- of paths that vanish at t_a, and the path integral solution (III.A–4) of the Schrödinger equation $\Psi(b,t_b)$ is over the space Ω_+ of paths that vanish at t_b. The solution of the diffusion equation is computed over the probability space $(\Omega_-, \mathcal{F}, \mu_s)$

$$\Psi(a,t_b) = \int_{\Omega_-} d\mu_s(\omega)\exp\Big(\frac{1}{\mu^2 s}\,\frac{1}{m}\int_{t_a}^{t_b} V\Big(\Pi\big(x(t)\big)\Big)dt\Big)\varphi\Big(\Pi\big(x(t_b)\big)\Big)\,. \tag{III.A–3}$$

It suggests that the solution of the Schrödinger equation[6]

$$\Psi(b,t_b) = \int_{\Omega_+} d\mu_s(\omega)\exp\Big(\frac{1}{\mu^2 s}\,\frac{1}{m}\int_{t_a}^{t_b} V\Big(\Pi\big(x(t)\big)\Big)dt\Big)\varphi\Big(\Pi\big(x(t_a)\big)\Big) \tag{III.A–4}$$

be computed on the projective system $(\Omega_+, \mathcal{Q}, \mu_s)$ defined in section I.A. The Fourier transform of μ_s is (I.A–19)

$$\mathcal{F}\mu_s(\omega') = \exp\Big(-\frac{s}{2}\int_T d\omega'_\alpha(t)\int_T d\omega'_\beta(s)\,G_\pm^{\alpha\beta}(t,s)\Big)\ . \tag{III.A–5}$$

$$\text{For } \mu_s \text{ on } \Omega_+\,,\quad G_+^{\alpha\beta}(t,s) = \delta^{\alpha\beta}\inf(t_b - t, t_b - s)\ ; \tag{III.A–6a}$$

$$\text{For } \mu_s \text{ on } \Omega_-\,,\quad G_-^{\alpha\beta}(t,s) = \delta^{\alpha\beta}\inf(t - t_a, s - t_a)\ . \tag{III.A–6b}$$

In Section III.A, we give the piecewise linear approximation of (III.A–3), and in Section III.B, we give the semiclassical approximations of (III.A–4). A little bit of tedious bookkeeping gives the other cases.

A. Piecewise Linear Approximations

1. The piecewise linear approximations of the path integrals (II.B–25) or (III.A–3). They have been obtained by replacing a Brownian path z by its piecewise linear approximation z_Π for a partition $\Pi = (t_a, t_1, \ldots, t_k = t_b)$.

$$z_\Pi : T = [t_a, t_b] \times \Omega \to \mathbb{R}^n$$

by

$$z_\Pi(r,\omega) = (\Delta_j\, t)^{-1}\big((t_{j+1} - r)\,z(t_j,\omega) + (r - t_j)\,z(t_{j+1},\omega)\big) \tag{III.A–7}$$

[6] If there is a term proportional to $A_\alpha \partial\psi/\partial x^\alpha$ in the equations, the corresponding terms in the solutions (III.A–3) and (III.A–4) are affected by opposite signs. For details, see DeWitt-Morette and Elworthy (1978).

for $t_j \leq r \leq t_{j+1}$ and $\Delta_j t = t_{j+1} - t_j$. The basic theorems for piecewise linear approximations have been developed by Elworthy (1982) and Elworthy and Truman (1981). The detailed calculation of the piecewise linear approximation I_k of (III.A–3) can be found in DeWitt-Morette and Elworthy (1978).

$$I_k = \int_{\mathbb{R}^{nk}} \overline{K}(k;k-1)\,\overline{K}(k-1;k-2)\ldots\overline{K}(1;0)\,\varphi(q_0)\,dv(q_0)\ldots dv(q_{k-1}) \tag{III.A–8}$$

where $dv(q_j)$ is the Riemannian volume element

$$dv(q_j) = \left(|g(q_j)|\right)^{1/2} dq_j^1 \ldots dq_j^n \ ,$$

g being the determinant of the metric tensor, and

$$\overline{K}(j+1;j) = \left(\frac{m}{2\pi s\hbar}\,\Delta_j t\right)^{n/2} \mathcal{D}(j+1;j)\,\exp\left(\frac{s}{\hbar}\,S(j+1;j)\right) \ . \tag{III.A–9}$$

$S(j+1;j)$ is the action function evaluated along the geodesic from (q_j, t_j) to (q_{j+1}, t_{j+1}), and $\mathcal{D}(j+1;j)$ is the absolute value of the invariant Van Vleck determinant for the action $S(j+1;j)$

$$\mathcal{D}(j+1;j) = (\Delta_j t)^{-n}\, g^{-1/2}(q_{j+1})\, g^{-1/2}(q_j) \left| \det_{\alpha\beta} \frac{\partial(\exp^{-1}_{q_{j+1}})^\alpha(q_j)}{\partial q_j^\beta} \right| \tag{III.A–10}$$

where $\exp_{q_{j+1}} : T_{q_{j+1}}M \to M$ and $D(\exp^{-1}_{q_{j+1}})(q_j) : T_{q_j}M \to T_{q_{j+1}}M$. It has been shown (eq. (6.38) in DeWitt (1957)) that

$$\mathcal{D}(j+1;j) = (\Delta_j t)^{-n}(1 + \tfrac{1}{6}\, R_{\alpha\beta}\, \Delta_j q^\alpha\, \Delta_j q^\beta + \cdots) \tag{III.A–11}$$

where $\Delta_j q = q_{j+1} - q_j$ and R is the Ricci tensor.

I had been expecting not the Van Vleck determinant but its square root. However, checking and rechecking the long calculation of (III.A–4) when z is replaced by its piecewise linear approximation (III.A–7) did confirm (III.A–10). My expectation was based on the erroneous assumption that one can use the WKB approximation of the propagator for its short-time approximation ($\overline{K}(j+1;j)$. But all we can say, *a priori*, is that if K is the exact propagator, then $\overline{K}$ such that

$$K(j+1;j) = \overline{K}(j+1;j)\left(1 + O(\Delta_j t)^2\right) \tag{III.A–12}$$

is a good choice.

2. A semihistorical summary of other piecewise linear approximations. In the early fifties, it was thought that the WKB approximation of the exact propagator K was a good choice for $\overline{K}$ for the following reasons:

a) It was obtained (Morette, 1951) in the flat case by requiring probability conservation (i.e., unitarity): if the L_2-norm of the initial wave function ψ_0 is unity,

requiring the L_2-norm of the wave function ψ at time $t_0+\varepsilon$ to be unity and ignoring terms of order Δx^2 and $\Delta x\,\Delta t$ leads to $|\overline{K}|^2 = |K_{\rm WKB}|^2$ where

$$K_{\rm WKB}(j+1;j) = (m/2\pi i\hbar)^{n/2}\,\mathcal{D}^{1/2}(j+1;j)\exp\left(\frac{i}{\hbar}\,S(j+1;j)\right)\ .$$

b) Since $K = K_{\rm WKB}\big(1+0(\Delta_j\,t)^2\big)$ for many physical systems (Pauli, 1952), it was assumed that $\overline{K}$ could be taken equal to $K_{\rm WKB}$.

However, when the configuration space is a Riemannian manifold, DeWitt (1957) showed that for a system with Lagrangian

$$L=\tfrac{1}{2}m|\dot{q}|^2-V(q)\,;\ \ H=\langle p,q\rangle-L\,;\ \ \widehat{H}=\frac{1}{2m}g^{-1/4}\,p_i\,g^{1/2}g^{ij}p_j\,g^{-1/4}+V(q)$$

if one chooses $K = K_{\rm WKB}$, the limit of I_k—if its exists—should satisfy the Schrödinger equation

$$i\hbar\partial\psi_+/\partial t = \widehat{H}_+\,\psi_+ \qquad \text{with} \qquad \widehat{H}_+ = \widehat{H} + \tfrac{1}{12}\hbar^2 R$$

where R is the Riemann curvature scalar. It is often thought that the Correspondence Principle favors this choice. The original remark by DeWitt (1957) said only, "The quantum theory that one arrives at by applying the Correspondence Principle via [choosing $\overline{K}$ to be the W. K. B. approximation] is determined not by the operator $\widehat{H}$ but by the operator $\widehat{H}_+$." Moreover, DeWitt (1957) also showed that if one chooses $\overline{K}$ equal to the simplest guess one can make, namely, $\overline{K}(j+1,j) = (m/\Delta_j\,t2\pi i\hbar)^{n/2}\,\exp\big(\frac{i}{\hbar}\,S(j+1;j)\big)$, then for the same Lagrangian, the limit of I_k should satisfy

$$i\hbar\partial\psi_{++}/\partial t = \widehat{H}_{++}\,\psi_{++} \qquad \text{with} \qquad \widehat{H}_{++} = \widehat{H} + \tfrac{1}{6}\hbar^2 R\ .$$

Both $\widehat{H}_+$ and $\widehat{H}_{++}$ agree with $\widehat{H}$ when $\hbar$ tends to zero and are self-adjoint when $\widehat{H}$ is self-adjoint, i.e., both schemes are unitary.

If one had insisted that, for a system whose classical Lagrangian and Hamiltonian are L and H, the canonical pair $(L,\widehat{H})$ was to be preferred over the pairs $(L,\widehat{H}_+)$ or $(L,\widehat{H}_{++})$, one would have said

$$\overline{K}(j+1;j) = (m/2\pi i\hbar\Delta_j\,t)^{n/2}\Big(1+\frac{1}{6}R_{\alpha\beta}\,\Delta_j\,q^\alpha\,\Delta_j\,q^\beta\Big)\exp\Big(\frac{i}{\hbar}S(j+1;j)\Big)\,, \tag{III.A–13}$$

i.e., an expression which agrees with (III.A–9), (III.A–11), but one would not have thought of (III.A–9), which looks wrong to anyone expecting K to be $K_{\rm WKB}$.

Formally, $\overline{K}(j+1;j)$ given by (III.A–13) can be replaced by

$$K_{\rm WKB}(j+1;j)\exp\big(\tfrac{1}{12}\,R_{\alpha\beta}\,\Delta_j\,q^\alpha\,\Delta_j\,q^\beta\big)$$

and in the Feynman integral, where $\Delta q^\alpha\,\Delta q^\beta$ can be replaced by $i(\hbar/m)\delta^{\alpha\beta}\Delta t$, by

$$K_{\rm WKB}(j+1;j)\,\exp\left(\frac{i}{12}\,\frac{\hbar}{m}\,\Delta_j\,t\,R\right)\ , \qquad \text{i.e., } K_{\rm WKB}\times\text{ phase}\,.$$

Thus, $|\overline{K}| = |K_{\rm WKB}|$ but $\overline{K}$ is not necessarily equal to $K_{\rm WKB}$; this is precisely the mistake made "in the early fifties."

B. Semiclassical Approximations

1. Strict[7] *WKB approximation of the path integral (III.A–4) defined by (II.A–3). The stochastic process* $x(t)$. If $x(t)$ were defined by an ordinary—rather than by a stochastic differential—equation (i.e., by (II.A–2b) rather than (II.A–3)), $\Pi(x(t))$ would be the Cartan development of a path in $\mathbb{R}^n$ (see exercise following (II.A–2b)), and one could use the properties of the development map, Dev, to compute the path integral. One could proceed as follows. Let

$$\text{Dev: Space of paths on } \mathbb{R}^n \to \text{space of paths on } M$$

by $z \mapsto \text{Dev}\, z$. Set

$$X(t,z) = (\text{Dev}\, z)(t) \ , \tag{III.B–1}$$

then rewrite (III.A–4)

$$\Psi(b,t_b) \ = \int_{\Omega_+} d\mu_s(\omega) \exp\Big(\frac{1}{\mu^2 s}\,\frac{1}{m}\int_{t_a}^{t_b} V\big(X(t,b+\mu z)\big)\,\varphi\big(X(t_a,b+\mu z)\big)\Big) \tag{III.B–2}$$

and expand the right-hand side in powers of $\mu = (\hbar/m)^{1/2}$ (I.B–12). The result would be the semiclassical expansion of $\Psi(b,t_b)$. The WKB approximation could be computed explicitly with the linear methods presented in Section I.B.1 because the derivative of any map (in particular, the development map) is linear. To compute $\Psi(b,t_b)$ one needs to choose the initial wave function φ.

To compute the WKB approximation of Ψ, a natural choice for φ, first proposed by Truman (1976, 1977), is

$$\varphi(\cdot) = \exp\Big(\frac{i}{\hbar}\,S_0(\cdot)\Big)\,T(\cdot) \ , \tag{III.B–3}$$

where T is an "arbitrary" function on M whose support determines the localization of the system and S_0 is the initial value of the solution of the Hamilton-Jacobi of the system with potential V.

Embarrassingly, this illegitimate procedure (using the smooth Cartan development map rather than the measurable stochastic development map) has been used (DeWitt-Morette et al, 1979). The result is in agreement with the stochastic calculation of Elworthy and Truman (1981) and Watling (1986) (see below).

$$\Psi_{\text{WKB}}(t_b,b) = \big(\det_{\alpha\beta}\partial Z^\alpha(t_a)/\partial Z^\beta(t_b)\big)^{1/2}\exp\Big(\frac{i}{\hbar}\,\bar{S}(t_b,b)\Big)\,T\big(Z(t_a)\big) \tag{III.B–4}$$

[7] We call WKB approximation the first meaningful term of a semiclassical expansion, and "strict" WKB the first term when it happens to be of the form $(\det)^{1/2}\exp(\frac{1}{\hbar}$ classical action), i.e., when the critical points of the action are not degenerate (no caustics).

where $\bar{S}$ is the action function computed for the classical path Z on M

$$m g_{\alpha\beta}\, \ddot{Z}^{\beta}(t) + \nabla_{\alpha}\, V\big(Z(t)\big) = 0 \tag{III.B–5a}$$

satisfying the following boundary conditions

$$\begin{cases} Z(t_b) = b & \text{(III.B–5b)} \\ \nabla_{\alpha}\, S_0\big(Z(t_a)\big) = m g_{\alpha\beta}\,\big(Z(t_a)\big)\, \dot{Z}^{\beta}(t_a)\ . & \text{(III.B–5c)} \end{cases}$$

The determinant in (III.B–4) gives the rate at which a flow of classical paths originating in a neighborhood of $S_0\big(Z(t_a)\big)$ diverges or converges. It reflects both the choice of the initial wave function (III.B–3) and the dynamical properties of the system (III.B–5a). The WKB approximation (III.B–4) is a "strict" WKB approximation, i.e., valid only if the flow up to time t_b of classical paths originating in a neighborhood of $S_0\big(Z(t_a)\big)$ has an inverse: The flow of classical paths on M is a map

$$\Phi_t : M \to M \qquad \text{by} \qquad a \mapsto Z(t, a) \tag{III.B–6}$$

where $Z(\cdot\,, a)$ is a classical path originating at a. The result (III.B–4) is very plausible—indeed, so plausible that some physicists would think the long calculation leading to it unnecessary. On the other hand, mathematicians[8] would think it unreliable.

I shall now present briefly[9] a legitimate calculation of the WKB approximation of (III.A–3). Minor modifications would give the approximation (III.B–4) of (III.A–3). For a discussion of flows of stochastic dynamical systems, see Carverhill and Elworthy (1983) and Elworthy (1982).

Elworthy (1982) has shown that the stochastic equation (II.A–3) defines a "stochastic development" from the space of Brownian paths defined on a fixed tangent space T_aM (or T_bM if preferred) to the space of paths on M—a path and its development beginning at a (respectively ending at b). The stochastic development map is measurable (not differentiable), and one can apply the Girsanov-Cameron formula to (III.A–3). The Girsanov-Cameron-Martin formula gives the flexibility of writing two versions of a path integral, one in terms of a process x, the other in terms of a process $\bar{x}$. I shall present the procedure on $\mathbb{R}^n$ in a form easy to generalize and choose $\bar{x}$ such that one can easily write down semiclassical expansions. Let

$$\begin{cases} dx_t \ = \mu\, dz_t\,,\ \mu = \sqrt{\hbar/m}\ \text{(not to be confused with the integrator } \mu\,!) \\ v_t \ = \exp \displaystyle\int_0^t V(x_s)\, ds \end{cases} \tag{III.B–7}$$

[8] Having in a first draft of this calculation excused my use of (II.A–3) as if it were (II.A–2b) with the conventional "By a convenient abuse of language," my mentor (K.D.E.) wrote back, "That 'convenient abuse of language' phrase is almost as strong an abuse of the word 'convenient' as the Mafia could ever have made, since it knocks out one of the major mathematical difficulties!"

[9] This presentation is based on unpublished lectures given by Elworthy at Les Houches in 1983.

be the flat space version of (II.B–24); let Y be an arbitrary map: $\mathbb{R}^n \to \mathbb{R}$, which will be chosen later so that the path integral expressed in terms of the potential V may be restated as a path integral in terms of the action S; and let

$$\begin{cases} d\bar{x}_t &= \mu\, dz_t + \nabla Y(\bar{x}_t)\, dt \equiv \mu\, dz_t + \nabla Y_t\, dt \ , \qquad \bar{x}_0 = x_0 \ ; \\ dv_t &= \exp \int_0^t V(\bar{x}_s)\, ds \ . \end{cases} \tag{III.B–8}$$

Then,

$$\Psi(x_0, t) = \int_\Omega \Big(M_t \exp\big(\int_0^t V(y_s)\, ds \big) \varphi(y_t) \Big)\, d\mu(\omega) \ , \qquad M_b = 1 \ , \tag{III.B–9}$$

solves (II.B–26) when $M = \mathbb{R}^n$, with

$$M_t = 1 \ , \qquad y_t = x_t \text{ given by (III.B–7)}, \tag{III.B–10}$$

or

$$\begin{cases} M_t &= \exp\Big(\frac{1}{\mu^2} \big(Y(x_0) - Y(\bar{x}_t) \big) \\ &\qquad + \frac{1}{\mu^2} \int_0^t \Big(\frac{\partial Y}{\partial s}(\bar{x}_s) + \frac{1}{2} \|\nabla Y(\bar{x}_s)\|^2 + \frac{1}{2} \nabla Y_s(\bar{x}_s) \Big)\, ds \Big) \\ y_t &= \bar{x}_t \text{ given by (III.B–8)}. \end{cases} \tag{III.B–11}$$

We choose the apparently more intractable version (III.B–11) because we can choose Y to yield computable semiclassical approximations. Elworthy made the following choice suggested by classical mechanics. Recall the equations of classical mechanics. Let $\Phi : M \to M$ be defined

$$\begin{cases} \dot{\Phi}_s(a) &= -\nabla V\big(\Phi_s(a)\big) \ , \\ \Phi_0(a) &= a \ , \quad \dot{\Phi}_0(a) = \nabla S_0(a) \ . \end{cases} \tag{III.B–12}$$

Assume Φ is a diffeomorphism for $0 \le s \le \tau$. Let $S : [0, \tau) \times M \to \mathbb{R}$ be the solution of the Hamilton-Jacobi equation

$$\frac{1}{2} \|\nabla S_t(a)\|^2 + V(a) + \frac{\partial S_t}{\partial t}(a) = 0 \tag{III.B–13}$$

such that S_0 is precisely the function S_0 in (III.B–12). Then

$$\dot{\Phi}_t(a) = \nabla S_t\big(\Phi_t(a)\big) \ .$$

For $t < \tau$, set[10]

$$Y_s(a) := -S_{t-s}(a) \ , \quad 0 \le s \le t \ . \tag{III.B–14}$$

[10] This and (III.B–17) are the complications announced earlier (I.B–18) because the Brownian path z in (III.B–7) and (III.B–8) vanish at time $t = 0$; the reversal (III.B–14) would not be necessary if the paths z were to vanish at the final time. In Carverhill and Elworthy (1983) and Elworthy (1988), much of the work is done with z vanishing at the final time.

Then, with the choice (III.B–11) and the initial distribution (III.B–3), the limit of (III.B–9) is

$$\Psi_{\mathrm{WKB}}(x_0,t) = \exp\Big(-\frac{1}{\mu^2}S_t(x_0)\Big)\int_\Omega \exp\Big(-\frac{1}{2}\int_0^t \Delta S_{t-s}(\bar{x}_s)ds\Big)T(\bar{x}_t)d\mu(\omega)\,, \tag{III.B–15}$$

which is the same, *mutatis mutandis*, as (III.B–4) because

$$\Delta S_{t-s}(\Theta_s(a)) = \frac{\partial}{\partial s}(\log\det T_{\Theta_s(a)}\,\Phi_{t-s}^{-1}) \tag{III.B–16}$$

where Φ is defined by (III.B–12),

$$\Theta_s(a) = \Phi_{t-s}(\Phi_t^{-1}(a))\ ,\quad \dot{\Theta}_s(a) = -\nabla S_{t-s}(\Theta(a))\ . \tag{III.B–17}$$

To obtain the next term in the expansion in μ^2 of (III.B–9) with the choice (III.B–11), Watling (1986) chose Y of the form

$$Y_s = -S_{t-s} + \mu^2 \log U_{t-s}$$

with

$$U_s(a) = T_0(\Phi_t^{-1}(a))\,(\det T_a\Phi_s^{-1}(a))^{1/2}\ .$$

So far, we have assumed the classical flow $\Phi_s : M \to M$ to be a diffeomorphism, at least for $s < \tau$. What happens if the classical flow does not have an inverse?

2. "When strict WKB breaks down". Classical paths are critical points of the action. When the critical points are degenerate, strict WKB breaks down. This can happen for several reasons, depending on the nature of the degeneracy of the critical point. For instance, the classical flow on the configuration space can be caustic forming.

In the example quoted in Section I.A, glory scattering, the critical points of the action (i.e., the classical paths) are degenerate for two reasons:

i) The classical paths are characterized by an initial momentum and a final momentum constrained by the energy conservation law—a consequence of the invariance of the system under time translation.

ii) The geometry of glory scattering: Two paths with different impact parameters, in the neighborhood of the glory impact parameter can have the same initial momentum and final momenta equal "to first order," i.e., a caustic situation in phase space.

The degeneracies have been classified (DeWitt-Morette, 1984) and much is known about WKB on and beyond the caustics. Such WKB approximations are not "strict" WKB approximations. They give quantitative answers to several phenomena: glories, rainbows, conservation laws. See references in DeWitt-Morette (1984) and DeWitt-Morette (1987).

Figure 6. For a point in the "dark" side of the caustic there is no classical path; for a point on the "bright" side there are 2 classical paths that coalesce into a *single* one as the intersection of the 2 paths approaches the caustic. Note that the paths do not arrive at an intersection at the same time, the paths do not intersect in a space-time diagram.

Figure 7. A flow on configuration space of charged particles in a repulsive Coulomb potential.

3. Nonanalyticity of WKB approximations. In this course we have discussed diffusion and Schrödinger equations. Their solutions can be analytically continued one in the other—which, as we have emphasized in Section I.A, is not to say that their integrators can be analytically continued. But the WKB approximations of their solutions cannot be analytically continued because the limit $\hbar = 0$ is a singular limit. A very instructive example has been analyzed by Michael Berry (to appear)—concerns the sex life of moths: male moths use their sense of smell to find their ways to the females. According to a WKB approximation (small diffusion coefficient) of the diffusion equation for the usual environment, the males can be successful sufficiently often. According to an analytic continuation starting from the WKB approximation of the corresponding Schrödinger equation, they cannot.

IV. CONCLUSION

I have presented the tools to solve problems of quantum mechanics in curved spacetimes:

i) Choose the stochastic process on a frame bundle that describes your system.

ii) Choose your initial wave function.

iii) A stochastic process together with an initial wave function defines a path integral on the projective system $(\Omega, \mathcal{O}, \mu)$.

iv) Compute the path integral.

But I have presented only one application, namely, the glory scattering of waves by black holes—a classical wave problem identical to a quantum mechanical problem when the waves are monochromatic. There are many challenging problems waiting to be done. To mention but one: paths which take their values in spacetime have unique properties; e.g., some preliminary calculations indicate that when the flow of spacetime classical paths is caustic forming, the system may undergo pair productions and pair annihilations. It would be interesting to compute the corresponding path integral—i.e., the path integral with a potential and an initial wave function such that the corresponding classical system defines a caustic forming flow.

I am sure that many problems presented in this course can be stated in terms of stochastic processes on fibre bundles and solved accordingly. Thank you for your attention.

ACKNOWLEDGEMENT

Discussions with Askell Hardarson and Ubirajara van Kolck have been enjoyable and profitable.

APPENDIX: SELECTED REFERENCES TO OTHER APPROACHES

I had hoped to include an appendix titled "Other Approaches to Defining Feynman Path Integrals." I had planned to begin with (in no particular order) Itô's definition, nonstandard analysis, Nelson-Trotter formulae, product integrals (Dollard-Friedman), Green functions (loop expansions), oscillatory integrals (Albeverio-Hoegh Krohn), polygonal approximations (lattice approximations, time

slicing, discretization), analytic continuations (in time, in mass, in Planck's constant), coherent states, group theoretical approaches, partition of unity, Meiman's rough measures, Brownian motion on the circle, spinor chain—to name only the ones that come readily to my mind without going to the library. It quickly became clear that this project was far too ambitious, given the time available. I shall only mention a few references, which I have found particularly helpful as a starting point; most of them include excellent references for further (or prior) study. In chronological order:

MUTUALLY INTERACTING QUANTUM FIELDS IN CURVED SPACE-TIMES: THE OUTCOME OF PHYSICAL PROCESSES

Jürgen Audretsch
Fakultät für Physik
Universität Konstanz
Postfach 55 60
D-7750 Konstanz
West Germany

INTRODUCTION

During the last years many efforts have been made to study quantum field theory in given unquantized space-times. This external field approach for the influence of classical gravitational fields is generally regarded as some sort of semi-classical approximation to a full quantum theory of gravity. It is assumed that characteristic physical traits which show up in this approximation will be at least heuristically important for the construction of the full theory. Furthermore the approximation has its own domain of application during the very early stages of the universe and outside black holes.

In the following we will restrict ourselves to the discussion of the quantum field theory of several quantum fields which are mutually interacting in the presence of an external gravitational field represented by the curvature of space-time. The intention is thereby i.) to contribute to the development of an appropriate conceptual framework (what are the measurable quantities, what is the related calculation scheme?), ii.) to work out the physical characteristics of such a theory (including a discussion of advantages and deficiencies of the respective schemes) and iii.) to answer questions like: How are the minkowskian cross sections and decay rates modified? Exact solvability will be given preference over physical applicability. At present the conceptual framework and the

Quantum Mechanics in Curved Space-Time
Edited by J. Audretsch and V. de Sabbata
Plenum Press, New York, 1990

understanding of the new typical physical effects still need improvement. Examples have therefore to support first of all the intentions i.) and ii.). To keep close to the reliable ground of special relativistic procedures, we restrict to a treatment in the interaction picture using an S-matrix approach whereby the background is always taken into account exactly (Furry picture).

Non-minkowskian situation

Quantum field theory in curved space-time is a special case of a non-minkowskian situation in quantum field theory. This situation is characterized by the existence of two different definitions of particles based on different operational procedures and usually attributed to two different kinds of observers. We will call these observers in- and out-observers because we will specialize below to a scattering situation. For simplicity we discuss real Klein-Gordon fields. A Klein-Gordon inner product (,) is attributed to a class of timelike hypersurfaces.

The in-observer specifies his particle concept in defining a complete orthonormal set $\{u^{in}_{\underline{p}}\}$ of Klein-Gordon solutions as those which describe to particles according to his measuring procedure: $(u^{in}_{\underline{p}}, u^{in}_{\underline{q}}) = \delta_{\underline{p}\underline{q}}$ $\underline{p}$ denotes some set of quantum numbers. The quantized real field may be decomposed with regard to the respective creation and annihilation operators:

$$\Phi = \sum_{\underline{p}} [a^{in}_{\underline{p}} u^{in}_{\underline{p}} + a^{in\dagger}_{\underline{p}} u^{in*}_{\underline{p}}] \tag{1}$$

We quantize the system in the usual way (canonical quantization)

$$[a^{in}_{\underline{p}}, a^{in}_{\underline{q}}] = 0 \quad , \quad [a^{in}_{\underline{p}}, a^{in\dagger}_{\underline{q}}] = \delta_{\underline{p},\underline{q}} \tag{2}$$

set up an in-Fock space and define the vacuum state as usual:
$a^{in}_{\underline{p}} |0 \text{ in}> = 0$.

We proceed in the same way with regard to the second observer, who bases his particle concept on the solutions $\{u^{out}_{\underline{p}}\}$,which are also orthonormal and complete $(u^{out}_{\underline{p}}, u^{out}_{\underline{q}}) = \delta_{\underline{p},\underline{q}}$. we quantize corresponding to (2) and obtain in addition to (1) a second decomposition of the field operator:

$$\Phi = \sum_{\underline{p}} [a^{out}_{\underline{p}} u^{out}_{\underline{p}} + a^{out\dagger}_{\underline{p}} u^{out*}_{\underline{p}}] \tag{3}$$

The vacuum state of the related Fock space is characterized by $a^{out}_{\underline{p}} |0 \text{ out}> = 0$.

The physical situation is generically non-minkowskian, if the two particle concepts don't agree: $u^{in}_{\underline{p}} \neq u^{out}_{\underline{p}}$. The immediate consequence is $a^{in}_{\underline{p}} \neq a^{out}_{\underline{p}}$. For the existence of an S-matrix see Wald (1979). Equating (1) and (3), we can write the out-operators as functions of the in-operators (compare (15) and (16) below). Inserting this into the expression for the mean value of the number of out-particles in the in-vacuum

$$N^{(0)}(\underline{p},0) = <0 \text{ in}| N^{out}_{\underline{p}} |0 \text{ in}> = <0 \text{ in}| a^{out\dagger}_{\underline{p}} a^{out}_{\underline{p}} |0 \text{ in}> \neq 0 \tag{4}$$

we obtain that in general this mean value will not vanish. The important consequence is the observer dependence of the particle concept: The vacuum of the in-particles contains out-particles.

As a particular application of this observer dependence we discuss a scattering situation in which a curved space-time acts as an external field (figure 1). We assume that the curvature vanishes appropriately for the time-asymptotic hyperfaces Σ^{in} and Σ^{out} (cosmological situation). The particle definition is based on the quasi-free Klein-Gordon solutions $u^{in}_{\underline{p}}$ and $u^{out}_{\underline{p}}$ which are defined everywhere (we exclude horizons) and show a particle structure near the hypersurfaces Σ^{in} and Σ^{out} respectively. Usually the in-and out-solutions for the same $\underline{p}$ will differ. Note that

FIGURE 1

particles can only be defined asymptotically when there is no influence of the curved background and the particle concept is stable. This is an important restriction for the application of the scheme.

Equation (4) has a direct consequence in this situation: We assume that the in-region is empty. In the Heisenberg picture the corresponding vacuum state is also the state of the system in the out-region. According to (4) the out-region will then in general contain particles. Physically this means that also in the absence of mutual interaction between particles a non-vanishing space-time curvature radiates particles. As we will show below, this effect which happens in the absence of any possible mutual interaction between particles (zeroth order effect) influences severely all physical effects and the conceptual basis of quantum field theory in expanding universes and curved space-times in general.

Mutually interacting quantum fields in an unquantized cosmological background

We discuss the mutual interaction of two neutral scalar quantum fields:

$$L_I(\lambda, g_{\alpha\beta}, \Phi, \Psi) \tag{5}$$

We assume the field Φ to be massive, the field Ψ is massless. λ is the coupling parameter. The given unquantized curved space-time background with metric $g_{\alpha\beta}$ acts as an external field and is always exactly taken into account.

In the following we present case studies in which all the characteristic structural traits can be studied on the basis of mathematically relatively simple expressions which will be worked out rigorously. Generalizations to complex and fermionic field will be indicated. Physically such an the exact treatment of particular transitions according to the mutual interaction (5) may be regarded as a first step towards a detailed discussion of scalar quantum electrodynamics in curved space-time. Reviews of interacting quantum field theory in this context are given by Birrell (1981), Ford (1984) and Ford (1988).

We consider a 3-flat open Robertson-Walker universe. This topology is chosen because it is very likely to be realized in our universe and because we want to discuss genuine curvature effects leaving the influence of a non-trivial 3-topology apart. The space-time is conformally flat. We introduce the conformal time η

$$ds^2 = a^2(\eta)(d\eta^2 - d\underline{x}^2) \tag{6}$$

We treat the scattering processes in the presence of space-time curvature in the interaction picture. Back-reaction is excluded. To construct the physical particle states in the asymptotic regions, we assume according to the S-Matrix scheme that the mutual interaction is switched off adiabatically in the distant past and future:

$$\begin{aligned} S &= \lim_{\varepsilon \to 0} \hat{T} \exp[i \int L_I \exp(-\varepsilon|\eta|) d^4x] \\ &= 1 + iT = 1 + iT^{(1)} + iT^{(2)} + O(\lambda^3) \end{aligned} \tag{7}$$

ε is called the switch-off parameter and T denotes the time-ordering operator with regard to η. The different orders refer to the powers of the coupling parameter λ. This approach is close to the usual scheme in flat space-time. Note that because of (7) the mutual interaction is of infinite duration.

The particle field equations are the massive and massless conformally coupled Klein-Gordon equations $(\nabla_\mu \nabla^\mu + m^2 + R/6)\Phi = 0$. For take $m = 0$. R is the scalar curvature. Solutions of the field equations may be written in the form

$$u_{\underline{p}}(x) = (a(\eta))^{-1} f(\underline{p},\eta)\exp(i\underline{p}x) \tag{8}$$

where $f(\underline{p},\eta)$ satisfies the generalized oscillator equation

$$\partial_\eta^2 f(\underline{p},\eta) + (a^2(\eta)m^2 + \underline{p}^2)f(\underline{p},\eta) = 0 \tag{9}$$

$\underline{p}$ is the conserved momentum parameter. The measured momentum, as registered by the cosmic observer, is $p/a(\eta)$.

We assume that in the in- and out-region $(\eta = -\infty \;,\; \eta = +\infty)$ the curvature diminishes in such a way that the concept of stable particles can be introduced. This means that the solutions $\{u_{\underline{p}}^{in}\}$ and $\{u_{\underline{p}}^{out}\}$ approach essentially plane waves in the in- and out-region repectively. For a more precise discussion of the particle concept see Audretsch (1979) and Birrell and Davies (1982). Because of the conformal

invariance of the field equation, the solutions for the massless fields are proportional plane waves

$$f(\underline{k},\eta) \sim \exp(-ik\eta) \quad , \quad v_{\underline{k}}^{in} = v_{\underline{k}}^{out} = v_{\underline{k}} \tag{10}$$

with $k = |\underline{k}|$. In this case there is no influence of the curvature. The in- and out-particle solutions are the same for massless particles. Because of conformal invariance, the physics of the free massless particles agrees completely with the one in flat space-time. The mass of the massive particles on the other hand breaks conformal invariance. This will be important below.

We quantize as above. For Ψ-particles we replace $u \to v$, $\underline{p} \to \underline{k}$ $a \to b$ and have:

$$b_{\underline{k}}^{in} = b_{\underline{k}}^{out} = b_{\underline{k}} \quad , \quad |s^{\Psi} \text{ out} > \; = \; |s^{\Psi} \text{ in} > \tag{11}$$

The in-vacuum state is defined according to $a_{\underline{p}}^{in} \, |0 \text{ in} > \; = \; b_{\underline{k}} \, |0 \text{ in} > \; = \; 0$
For a general state vector we write

$$a_{\underline{p}}^{in\dagger} \ldots b_{\underline{k}}^{\dagger} \ldots |0 \text{ in} > \; = \; |1_{\underline{p}}^{\Phi} \ldots 1_{\underline{k}}^{\Psi} \ldots \text{ in} > \; = \; |e^{\Phi} s^{\Psi} \text{ in} > \tag{12}$$

e and s abbreviate a particular occupation of Φ- and Ψ-modes.

The information regarding the influence of the gravitational background is essentially contained in the Bogoliubov coefficients relating in- and out-particle solutions $\alpha_{\underline{p}} = (u_{\underline{p}}^{in}, u_{\underline{p}}^{out})$, $\beta_{\underline{p}} = (u_{\underline{p}}^{in}, u_{-\underline{p}}^{out*})$ with

$$|\alpha_{\underline{p}}|^2 - |\beta_{\underline{p}}|^2 = 1 \tag{13}$$

There would be a plus sign for fermionic fields. As consequence of the isotropy we have $\alpha_{-\underline{p}} = \alpha_{\underline{p}}$, $\beta_{-\underline{p}} = \beta_{\underline{p}}$. In- and out-particle solutions may be expressed with regard to each other:

$$u_{\underline{p}}^{out} = \alpha_{\underline{p}} \, u_{\underline{p}}^{in} + \beta_{\underline{p}}^{*} \, u_{-\underline{p}}^{in*} \quad , \quad u_{\underline{p}}^{in} = \alpha_{\underline{p}}^{*} \, u_{\underline{p}}^{out} - \beta_{\underline{p}}^{*} \, u_{-\underline{p}}^{out*} \tag{14}$$

Equating (1) and (3) we may write the in-operators as functions of

the out-operators and vice versa. We give this the form which will prove to be useful below:

$$a_{\underline{p}}^{in\dagger} = \alpha_{\underline{p}}^{-1} a_{\underline{p}}^{out\dagger} + \beta_{\underline{p}}^{*} \alpha_{\underline{p}}^{-1} a_{-\underline{p}}^{in} \tag{15}$$

$$a_{\underline{p}}^{out} = \alpha_{\underline{p}}^{-1} a_{\underline{p}}^{in} - \beta_{\underline{p}} \alpha_{\underline{p}}^{-1} a_{-\underline{p}}^{out\dagger} \tag{16}$$

Herewith the mixed commutator relations can be worked out:

$$[a_{\underline{p}}^{out}, a_{\underline{q}}^{in}] = \beta_{\underline{p}} \delta_{\underline{p},-\underline{q}} \, 1 \tag{17}$$

$$[a_{\underline{p}}^{out}, a_{\underline{q}}^{in\dagger}] = \alpha_{\underline{p}}^{*} \delta_{\underline{p},\underline{q}} \tag{18}$$

Inserting (15) in (4) the Bogoliubov coefficients obtain a direct physical interpretation related to the zeroth order particle creation out of the curved background:

$$N^{(0)}(\underline{p}^{\Phi}|0) = |\beta_{\underline{p}}|^2 \tag{19}$$

The specifications above (cosmological situation) have the following consequences: i.) Energy is not conserved ii.) There is a conserved 3-momentum parameter. iii.) Massive particles are created out of the vacuum in every momentum mode. iv.) Because of the conformal situation there is no corresponding creation of massless particles. A physical interpretation of quantum field theoretical processes has to be based on this.

MEASURABLE TRANSITION PROBABILITIES

In-out transition amplitudes

One is tempted to base the discussion of cross sections and decay rates as usual on in-out transition amplitudes built with the respective in- and out-states which contain a finite number of particles. If the mutual interaction is switched off completely, such an amplitude can be

reduced to the amplitude relating the in-vacuum with the out-vacuum according to

$$< \text{out } d^{\Phi}s^{\Psi}|c^{\Phi}r^{\Psi} \text{ in} > \; = \; F(\alpha,\beta) < \text{out } 0|0 \;\; \text{in} > \;\; \delta\text{-funct.} \tag{20}$$

This result is obtained by transcribing the out-operators according to (16) and using the commutator relations (17) and (18). F is a function of the Bogoliubov coefficients of the modes involved. For higher order we find (Audretsch and Spangehl, 1985):

$$<\text{out } d^{\Phi}s^{\Psi}|S^{(z)}| \; c^{\Phi}r^{\Psi} \text{ in}> \; =$$

$$\sum_{g,t} <\text{out } d^{\Phi}s^{\Psi}|g^{\Phi}t^{\Psi} \text{ in}><\text{in } \; g^{\Phi}t^{\Psi}|S^{(z)}|c^{\Phi}r^{\Psi} \;\; \text{in}> \tag{21}$$

by inserting

$$1 \; = \; \sum |g^{\Phi}t^{\Psi} \;\; \text{in} > < \text{in} \;\; g^{\Phi}t^{\Psi}| \tag{22}$$

where the sum is taken over all elements of the basis. When discussing (21), on the right hand side the result (20) is to be taken into account.

We introduce a normalization volume V. The function F of (20) proves then to be independent of the volume V. Parker (1969) on the other hand has shown, that in the cosmological case in question

$$|<\text{out } 0|0 \;\; \text{in}>|^2 \xrightarrow{V \to \infty} 0 \tag{23}$$

Accordingly we conclude from (20) and (21): For zero and all higher orders of the mutual interaction, any in-out probability amplitude becomes arbitrarily small for increasing normalization volume V. A single in-out amplitude loses its physical meaning for $V \to \infty$.

With regard to the physical interpretation this can be traced back to the fact that already in zeroth order the cosmological background creates massive particles in all modes. It is therefore impossible to find a completely empty out-state. This explains (23). For the same reason it is also impossible to find outgoing states with only a finite number of massive particle modes occupied and all other massive modes empty, regardless if there has been a mutual interaction between the two quantum fields or not. Consequently the transition probabilities related to (20) and (21) must vanish.

Indicator configurations and added-up probabilities

In addition there is an operational argument why in our case the general quantum field theoretical scheme for transition probabilities cannot be based on in-out amplitudes: A single particle counter for massive particles cannot discriminate between a particle coming out of the background and a particle originating from the mutual interaction. It is therefore impossible to specify the outcome of the mutual interaction on the basis of measurements with single counters for massive particles. The creation of massive particles out of the background necessarily interferes and cannot simply be separated.

To obtain nontrivial statements which refer as close as possible to the mutual interaction only, one has to fix the in-state and to concentrate on out-states which contain a specific indicator configuration, the appearance of which can clearly be determined by particle counters. Apart from the given in-state it is the outgoing indicator configuration by which the particular interaction process is then specified. An indicator configuration is thereby a configuration which cannot be produced by the background. It is therefore a direct consequence of the specific mutual interaction and contains the maximal information about the preceeding scattering process.

Massless particles are in our case good indicators because they are neither influenced nor created by the background. The concept of the general added-up transition probability (Audretsch and Spangehl, 1985) is based on this:

$$w^{add}\,(s^{\Psi}|c^{\Phi}r^{\Psi}) \;=\; \sum_{\text{all } d} |\langle \text{out } d^{\Phi}s^{\Psi}|S|c^{\Phi}r^{\Psi} \;\; \text{in}\rangle|^2 \qquad (24)$$

It answers the question: What is the probability that a particular state of massless particles $|s^{\Psi} \;\; \text{out}\rangle$ will be found in the out-region regardless of what has happened to the massive state and what massive states are going out. With $\sum_{\text{all } d} |d^{\Phi} \;\; \text{out}\rangle \langle \text{out} \;\; d^{\Phi}| = \sum_{\text{all } d} |d^{\Phi} \;\; \text{in}\rangle \langle \text{in} \;\; d^{\Phi}|$ the added-up probability w^{add} can be reduced to in-in amplitudes

$$w^{add}\,(s^{\Psi}|c^{\Phi}r^{\Psi}) \;=\; \sum_{\text{all } d} |\langle \text{in } d^{\Phi}s^{\Psi}|S|c^{\Phi}r^{\Psi} \;\; \text{in}\rangle|^2 \qquad (25)$$

This guarantees that for any given finite order of the mutual interaction the sum over the massive states stops, ending with states containing only a particular number of massive particles. In lower order only very few

amplitudes are to be considered similar to flat space-time quantum field theory.

In the expression (24) we sum up over all massive out-states. To obtain more specific answers and to improve the predictive power of the scheme, we may include good massive indicators. In our case we have conservation of the 3-momentum parameter. Accordingly the background creates massive particles only in pairs. Below we will demonstrate in detail, that also processes in higher order are influenced by the appearance of additional massive pairs. All configurations without massive pairs consist therefore of particles which originate from the interaction only (indicator state). The specified added-up probability that a transition into a state containing certain massless particles and unpaired massive particles has occurred - regardless of the creation of massive pairs out of the background or the mutual interaction - is given by:

$$w^{inc}\,(\hat{d}^{\Phi}s^{\Psi}|c^{\Phi}r^{\Psi}) \;=\; \sum_{\text{all } Q} |\langle \text{out } Q^{\Phi}\hat{d}^{\Phi}s^{\Psi}|S|c^{\Phi}r^{\Psi} \text{ in}\rangle|^2 \qquad (26)$$

Capital letters denote states which contain only pairs of massive particles. The sum goes over all these states. We call this probability the pair-including probability. It has been shown by Audretsch and Spangehl (1987) that it can be reduced to in-in amplitudes:

$$w^{inc}\,(\hat{d}^{\Phi}s^{\Psi}|c^{\Phi}r^{\Psi}) \;=\; \sum_{\text{all } Q} |\langle \text{in } Q^{\Phi}\hat{d}^{\Phi}s^{\Psi}|S|c^{\Phi}r^{\Psi} \text{ in}\rangle|^2 \qquad (27)$$

The probabilities (25) and (27) are the basis of an in-in quantum field theory which can be built up in close analogy to what is known from minkowskian quantum field theory. Essentially the special-relativistic creation and annihilation operators are to be replaced by in-operators and the minkowskian particle solutions (e.g. plane waves) by in-particle solutions. Note that in-in scheme does not mean that it is superfluous to specify the out-particle solutions. The appearance of Bogoliubov coefficients in the results below will demonstrate this. In this scheme too, an in- and a properly defined out-region where particles are stable, is needed.

We can now establish for the in-in scheme a Feynman diagram technique with correspondingly transcribed Feynman rules. The massive Feynman propagator is thereby:

$$i\Delta_F^{in}(x,y) \;=\; \langle \text{in } 0|\hat{T}\phi^{in}(x)\phi^{in}(y)|0 \text{ in}\rangle \;=\; \phi^{in}(x)\phi^{in}(y) \qquad (28)$$

There is a Wick theorem for in-operators. Disconnected vacuum-vacuum graphs are removed, if necessary, by dividing the in-in amplitude by $\langle \text{in } 0|S|0 \text{ in}\rangle$.

Returning to the discussion of in-out amplitudes, we mention that the relative in-out amplitudes $\langle \text{out } d^{\Phi}s^{\Psi}|S^{(z)}|c^{\Phi}r^{\Psi} \text{ in}\rangle \langle \text{out } 0|0 \text{ in}\rangle^{-1}$ although possibly finite, have no direct operational meaning. Nevertheless they can be mathematically useful in the in-in scheme because according to (20) and (21). They essentially agree with single or summed in-in amplitudes.

OPTICAL THEOREM

Consequence of the unitarity

We show that the optical theorem for quantum field theory in curved space-time can be transcribed to the in-in scheme thus obtaining a direct physical interpretation by means of added-up probabilities.

The unitarity $S^{\dagger}S = 1$ of the S-operator implies with (7) $T^{\dagger}T = -i(T - T^{\dagger})$ and therefore $\langle \text{in } a|T^{\dagger}T|a \text{ in}\rangle = 2\text{Im} \langle \text{in } a|T|a \text{ in}\rangle$ Inserting (22) this leads to the <u>optical theorem</u> in curved space-time in an in-in formulation (Audretsch, 1988):

$$\sum_{\text{all } e,s} |\langle \text{in } e^{\Phi}s^{\Psi}|T|d^{\Phi}r^{\Psi} \text{ in}\rangle|^2 = 2\text{Im} \langle \text{in } d^{\Phi}r^{\Psi}|T|d^{\Phi}r^{\Psi} \text{ in}\rangle \tag{29}$$

This can directly be rewritten with added-up probabilities.

$$\sum_{\text{all } s} w^{\text{add}} (s^{\Psi}|d^{\Phi}r^{\Psi}) = 2\text{Im} \langle \text{in } d^{\Phi}r^{\Psi}|T|d^{\Phi}r^{\Psi} \text{ in}\rangle \tag{30}$$

For a given ingoing state the optical theorem relates the imaginary part of the in-in forward scattering amplitude with the total added-up transition probability into all massless states (sum over s) which can be reached from the in-state according to the interaction. Note that in the cosmological case we don't have energy conservation. In contrast to the minkowskian situation neither the left nor the right hand side will in general reduce to only one term. At the first glance the optical theorem therefore seems to be a rather unspecific relation of restricted use. We demonstrate in the following example that this is not the case.

Example: Emission of a massive particle in the $\Phi\Psi^2$-model

We study in second order the case of one ingoing massless particle and decompose the left hand side of (29) with respect to the contributing Feynman diagrams of figure 2.

$$\sum_{\text{all } e,s} |\langle \text{in } e^{\Phi}s^{\Psi}|T^{(1)}|1_{\underline{l}}^{\Psi} \text{ in}\rangle|^2 =$$

$$\sum_{\underline{k}} |\langle 2a\rangle|^2 + \sum_{\underline{q},\underline{t}} |\langle 2b\rangle|^2 + \sum_{\underline{q}} |\langle 2c\rangle|^2 \qquad (31)$$

The diagrams of figure 2b and 2c contribute because there is no energy conservation and the ingoing massless particle may pass through and

FIGURE 2a FIGURE 2b FIGURE 2c

reappear in the out-region with the same momentum parameter. The squared amplitudes on the r.h.s. of (31) may be given a physical interpretation within our scheme:

$$\sum_{\text{all } \underline{k}\neq\underline{l}} w^{\text{add}}\,(1_{\underline{k}}^{\Psi}|1_{\underline{l}}^{\Psi})^{(2)} = \sum_{\underline{k}} |\langle 2a\rangle|^2 \qquad (32)$$

$$\hat{w}\,(1_{\underline{l}}^{\Psi}\,1_{\underline{l}}^{\Psi})^{(2)} = \sum_{\text{all } \underline{q},\underline{t}} |\langle 2b\rangle|^2 + \sum_{\text{all } \underline{q}} |\langle 2c\rangle|^2 \qquad (33)$$

The latter is the probability that the ingoing massless particle can be found undisturbed among others in the out-region.

The right hand side of the optical theorem (29) is in our case of the form

$$\mathrm{Im}\ \langle \mathrm{in}\ 1^{\Psi}_{\underline{l}} | T^{(2)} | 1^{\Psi}_{\underline{l}}\ \mathrm{in}\rangle \ = \ \mathrm{Im}\ [\langle \mathrm{in}\ 0 | T^{(2)} | 0\ \mathrm{in}\rangle + \langle 3a\rangle + \langle 3b\rangle] \quad (34)$$

where the reference is made to figure 3

FIGURE 3a FIGURE 3b

The first term on the r.h.s. of (34) goes back to diagrams, where the ingoing massless particle runs through undisturbed (line without vertex, omitted in the figures). This term can further be elaborated in making use of the optical theorem (29) in second order but now for a vacuum state going in: $|d^{\Phi} s^{\Psi}\ \mathrm{in}\rangle \ = \ |0\ \mathrm{in}\rangle$.

$$2\mathrm{Im}\ \langle \mathrm{in}\ 0 | T^{(2)} | 0\ \mathrm{in}\rangle \ = \ \sum_{\mathrm{all}\ \underline{q},\underline{t}} |\langle 2b\rangle|^2 + \sum_{\mathrm{all}\ \underline{q}} |\langle 2c\rangle|^2 \quad (35)$$

Equating (31) and (34) according to (29), we obtain with (35) and (32) the result:

$$\sum_{\mathrm{all}\ \underline{k}\neq\underline{l}} w^{\mathrm{add}}(1^{\Psi}_{k} | 1^{\Psi}_{l})^2 \ = \ 2\mathrm{Im}\langle 3a\rangle + 2\mathrm{Im}\langle 3b\rangle \quad (36)$$

The left hand side may physically be interpreted as the total probability for the emission of a massive particle by a massless particle. Note that only the imaginary parts of the second order in-in selfenergy transitions of massless particles are to be worked out. This relation obtained within the in-in scheme is closest to the relation one is used to in the minkowskian situation.

Additional examples

There are more results which can be obtained in combining relations derived from the optical theorem (Audretsch 1988). For example the added-up probability for the annihilation of a pair of massless particles according to the interaction above can be reduced to the imaginary part of the amplitude for forward scattering of two massless particles where reference is made to figure 4.

FIGURE 4b

For applications of the optical theorem to scalar quantum electrodynamics in curved space-time see Audretsch (1989).

GRAVITATIONALLY INDUCED AMPLIFICATION AND ATTENUATION

Mean value of the particle number

We continue the discussion of the physics of mutually interacting quantum fields in non minkowskian situations in turning to the discussion of the role of the massive particles, i.e. of particles which show nonvanishing gravitational particle creation out of the vacuum in zeroth order of the mutual interaction. We will show that the curved background also contributes in a very specific way to the outcome of the interaction in higher order. The appropriate concept to study this is the mean number of outgoing particles

$$N(\underline{p}^{\Phi}|a) = \langle \text{in } a|S^{\dagger}N_{\underline{p}}^{\Phi\text{out}}\, S|a \text{ in}\rangle \tag{37}$$

if the ingoing state is $|a \text{ in}\rangle$. With (22) we rewrite this expression in

the form:

$$N(p^{\Phi}|a) = \sum_{\text{all } b,c} \langle \text{in } a|S^{\dagger}|b \text{ in}\rangle \langle \text{in } b|N^{\Phi\text{out}}_{\underline{p}}|c \text{ in}\rangle \langle \text{in } c|S|a \text{ in}\rangle \quad (38)$$

For later use it is helpful to express the out-particle mean number operator with (15) and (16) by in-operators. Making in addition use of (13) we obtain:

$$N^{\Phi\text{out}}_{\underline{p}} = N^{(0)}(\underline{p}^{\Phi}|0)1 + N^{\Phi\text{in}}_{\underline{p}} \underset{(-)}{+} N^{(0)}(\underline{p}^{\Phi}|0)\ \{N^{\Phi\text{in}}_{\underline{p}} + N^{\Phi\text{in}}_{-\underline{p}}\}$$

$$- \alpha^{*}_{\underline{p}}\beta^{*}_{\underline{p}}\ a^{\text{in}}_{\underline{p}}a^{\text{in}}_{-\underline{p}} - \alpha_{\underline{p}}\beta_{\underline{p}}\ a^{\text{in}\dagger}_{\underline{p}}a^{\text{in}\dagger}_{-\underline{p}} \quad (39)$$

The minus sign (-) is included to indicate the corresponding result for fermionic fields. For complex fields operators with index $-\underline{p}$ have to be replaced by antiparticle operators.

<u>Induced gravitational amplification and attenuation in the absence of mutual interaction (zeroth order)</u>

Inserting (39) in (37) with $S = 1$ we find

$$N^{(0)}(\underline{p}^{\Phi}|a) =$$

$$N^{(0)}(\underline{p}^{\Phi}|0) + n(\underline{p}^{\Phi}|a) \underset{(-)}{+} N^{(0)}(\underline{p}^{\Phi}|0)\ \{n(\underline{p}^{\Phi}|a) + n(-\underline{p}^{\Phi}|a)\} \quad (40)$$

where the occupation number

$$n(\underline{p}^{\Phi}|\underline{a}) = \langle \text{in } a|N^{\Phi\text{in}}_{\underline{p}}|a \text{ in}\rangle \quad (41)$$

indicates how many massive particles with parameters $\underline{p}$ are contained in the ingoing state $|a \text{ in}\rangle$. Again the minus sign (-) applies in the fermionic case.

The zeroth order result (40) agrees with the one of Parker (1969, 1971). It shows for vanishing mutual interaction that if the ingoing state is not the vacuum, there are additional more processes in addition to the gravitational particle creation (19) out of the vacuum. The mean-

ing of the three terms in (40) is: particle creation out of the vacuum, particles already contained in the initial state which have passed through the region of external influence and reappear in the out-region and finally, gravitationally induced amplification of the ingoing particle content. Fermions on the other hand show attenuation (minus sign).

Only non-empty modes cause the additional creation of particles out of the background. This makes it an induced process. It happens only if show this clearly: An asymmetry in the particle content of the outgoing $\underline{p}$- and $-\underline{p}$-mode can only be caused by the passed through particles of an

FIGURE 5

there is creation out of the vacuum, thus amplifying this process. Because of momentum conservation the amplification results in additional outgoing pairs. The difference

$$N^{(0)}(\underline{p}^{\Phi}|a) - N^{(0)}(-\underline{p}^{\Phi}|a) = n(\underline{p}^{\Phi}|a) - n(-\underline{p}^{\Phi}|a) \tag{42}$$

asymmetric initial state. Because of this additional creation of pairs ingoing particles in the mode $-\underline{p}$ induce creation in the mode $\underline{p}$. This explains the appearance of $n(-\underline{p}^{\phi}|a)$. See figure 5 for a schematic representation.

Because of the factor $|\beta_{\underline{p}}|^2$, which describes the spectral behaviour of the vacuum creation, the amplification is mode dependent. This factor demonstrates that the amplification is in our case of gravitational origin or goes back to the non-minkowskian situation whenever this is characterized by a particle creation out of the vacuum. In the example above there is no amplification for the massless particles. We summarize: In the absence of mutual interaction between several quantum fields the initial presence of bosons tends to increase the number of bosons created out of the background. For fermions the situation is reversed. Vacuum creation and amplification/attenuation describe the physics of the zeroth order completely.

Induced gravitational amplification and attenuation in processes of mutual interaction

With (37) and (39) we find in higher order the following result for (S = 0) a mutual or self-interaction:

$$N^{(z)}(\underline{p}^{\phi}|a) = \sum_{\text{all } b} |\langle \text{in } b|S|a \text{ in}\rangle|^2_{(z)}\, n(\underline{p}^{\phi}|b) + \tag{43}$$

$$+ N^{(o)}(\underline{p}^{\phi}|0)\, [\sum_{\text{all } b} |\langle \text{in } b|S|a \text{ in}\rangle|^2_{(z)} (n(p^{\phi}|b) + n(-\underline{p}^{\phi}|b))] + \mathrm{Re}(\beta^*_{\underline{p}}\sigma_{\underline{p}})$$

With (41) the first term represents a sum over the number of particles with parameter $\underline{p}$ in the state $|b \text{ in}\rangle$ (which can be reached according to the interaction) times the transition probability in the in-in scheme for an initial state $|a \text{ in}\rangle$ to go over into this state $|b \text{ in}\rangle$. This is exactly an expression of the structure one would obtain in the minkowskian situation. The square bracket in the second term contains the first term plus the corresponding one for the pair partners in the mode $-\underline{p}$. Compari-

son of the total second term in (43) term with the third term in (40) reveals a close structural and physical analogy so that we may interpret this term again as the <u>amplification term</u>. In the fermionic case it has a different sign and represents therefore attenuation. The third term in (43) with

$$\sigma_{\underline{p}} = -2\alpha^{*}_{\underline{p}} \sum_{\text{all } b} \langle \text{in } a|S^{\dagger}|b \text{ in}\rangle \langle \text{in } 1^{\phi}_{\underline{p}} 1^{\phi}_{-\underline{p}} b|S|a \text{ in}\rangle \tag{44}$$

has no correspondence in the zeroth order formula (40).

FIGURE 6

Keeping in mind that we are always describing one total coherent in-out process and that there is no particle interpretation as long as the interaction takes place, we may nevertheless visualize the structure of (43) in the following diagrammatic rule: "Let the mutual interaction happen completely within the in-region only and describe it accordingly by in-in transition amplitudes. Process now the corresponding particle outcome as in zeroth order in a twofold way: At first the particles in the $\underline{p}$-mode pass through into the out-region as in (40) to obtain the first term of (43). Secondly, these particles are amplified in the same way as

in (40) whereby a possible outcome in the $-\underline{p}$-mode contributes in a symmetric manner. This leads to the second term in (43). Finally the σ-term of (43) is to be added." See figure 6 for a schematic representation of this rule.

Comparison of the $\underline{p}$- with the $-\underline{p}$-mode

$$N(\underline{p}^{\Phi}|a) - N(-\underline{p}^{\Phi}|a) = \sum_{\text{all } b} |\langle \text{in } b|S|a \text{ in}\rangle|^2 [n(\underline{p}^{\Phi}|b) - n(-\underline{p}^{\Phi}|b)] \quad (45)$$

shows that an asymmetry can only be due to the mutual interaction. Amplification and the process leading to the σ-term happen as creation of $(\underline{p},-\underline{p})$ pairs.

Rewriting (43) as

$$N^{(z)}(\underline{p}^{\Phi}|a) =$$

$$\sum_{\text{all } b} |\langle \text{in } b|S|a \text{ in}\rangle|^2 {}_{(z)}n(\underline{p}^{\Phi}|b)\{1 + N^{(o)}(\underline{p}^{\Phi}|0)[1 + \frac{n(-p^{\Phi}|b)}{n(p^{\Phi}|b)}]\} \quad (46)$$

$$+ \mathrm{Re}(\beta^{*}_{\underline{p}}\sigma_{\underline{p}}) \ .$$

we see, that amplification acts as a mode dependent amplification factor. The minkowskian contributions contained in the in-in transition amplitude are altered in a multiplicative way. This fact may be responsible for considerable modifications.

Specified mean value of the particle number

In the expressions (40) and (43) only the in-state has been specified. To make the particle number a concept which describes particular processes, we improve the scheme as we have done it above for transition probabilities. We specify again not only the in- but also the umpaired massive and the massless part of the out-state (indicator state) and sum up over all massive pairs:

$$N(\underline{p}^{\Phi}|\hat{d}^{\Phi}s^{\Psi} \leftarrow c^{\Phi}r^{\Psi}) = \sum_{\text{all } Q} |\langle \text{out } Q^{\Phi}\hat{d}^{\Phi}s^{\Psi}|S|c^{\Phi}r^{\Psi} \text{ in}\rangle|^2 \; n(\underline{p}^{\Phi}|Q^{\Phi}\hat{d}^{\Phi}s^{\Psi}) \quad (47)$$

We call this the <u>specified mean number</u> $N(\underline{p}^{\Phi}|\leftarrow)$. Operationally it means that we will register the number of massive particles leaving the interaction in the mode $\underline{p}$ only if the specific process $\hat{d}^{\Phi}s^{\Psi} \leftarrow c^{\Phi}r^{\Psi}$ (accompagnied by outgoing massive particles) has happened. The definition

$$n(p^{\Phi}|Q^{\Phi}\hat{d}^{\Phi}s^{\Psi}) = \langle \text{in } Q^{\Phi}\hat{d}^{\Phi}s^{\Psi}|N_{\underline{p}}^{\Phi\text{in}}|Q^{\Phi}\hat{d}^{\Phi}s^{\Psi} \text{ in}\rangle \tag{48}$$

implies that we always count unpaired as well as paired massive particles because this reflects the actual measurement situation. Pairs created by gravitional induction are included and will lead to amplification in the bosonic case.

After some calculations (47) may be rewritten as

$$\begin{aligned} N(\underline{p}^{\Phi}|\hat{d}^{\Phi}s^{\Psi} \leftarrow c^{\Phi}r^{\Psi}) &= N^{(o)}(\underline{p}^{\Phi}|0)w^{\text{inc}}(\hat{d}^{\Phi}s^{\Psi}|c^{\Phi}r^{\Psi}) + \\ &+ \sum_{\text{all } Q} |\langle \text{in } Q^{\Phi}\hat{d}^{\Phi}s^{\Psi}|S|c^{\Phi}r^{\Psi} \text{ in}\rangle|^2 \{n(p^{\Phi}|Q^{\Phi}\hat{d}^{\Phi}s^{\Psi}) + \\ &+ N^{(o)}(p^{\Phi}|0)[n(\underline{p}^{\Phi}|Q^{\Phi}\hat{d}^{\Phi}s^{\Psi}) + n(-\underline{p}^{\Phi}|Q^{\Phi}\hat{d}^{\Phi}s^{\Psi})]\} + \text{Re}(\beta^{*}_{\underline{p}}\tilde{\sigma}_{\underline{p}}) \end{aligned} \tag{49}$$

with

$$\tilde{\sigma}_{\underline{p}} = -2\alpha^{*}_{\underline{p}} \sum_{\text{all } L} \langle \text{in } a|S^{\dagger}|L^{\Phi}\hat{d}^{\Phi}s^{\Psi} \text{ in}\rangle \langle \text{in } L^{\Phi}1^{\Phi}_{\underline{p}}1^{\Phi}_{-\underline{p}}\hat{d}^{\Phi}s^{\Psi}|S|a \text{ in}\rangle \tag{50}$$

The latter expression is more simple and vanishes in more cases than (44). We will make use of this fact below.

A detailed analysis shows that the first term in (49) refers to particles which originate solely from zeroth order particle creation out of the vacuum. But in this more specific version these particles are only counted if the indicator configuration is registered simultaneously in the out-region. In non-zero order we have to disregard this contribution. We call the rest of (49) $N^{\text{int}}(\leftarrow)$. The various terms in this expression show a clear correspondence to (43), so that the physical interpretation can be transcribed.

Example: Compton scattering in the $\Phi^2\Psi^2$-model and the pure amplification effect

To prove the usefulness of the concepts introduced above for the discussion of the underlying physical structure of processes of mutual interaction, we study second order Compton scattering in the $\Phi^2\Psi^2$-interaction. This will enable us to demonstrate a pure amplification process of higher order, i.e. a process to which the last term in (46) doesn't contribute. To do so we take $1^{\Phi}_{q}1^{\Psi}_{l}$ as initial state, $1^{\Phi}_{p}1^{\Psi}_{k}$ as indicator state for the outgoing particles and compare the number of outgoing massive particles in the mode $\underline{p}$ with the number of outgoing massless particles in the mode $\underline{k}$ (Audretsch and Spangehl, 1987).

The first observation is that $\bar{\sigma}^{(1)} = 0$ and $\bar{\sigma}^{(2)} = 0$ vanish, thus making the scattering a pure amplification effect. With (49) and using (19) we end up with two transition amplitudes:

$$N^{int}(\underline{p}^{\Phi}|1^{\Phi}_{\underline{p}}1^{\Psi}_{\underline{k}} \leftarrow 1^{\Phi}_{\underline{q}}1^{\Psi}_{\underline{l}})^{(2)} = \{|\langle in\ 1^{\Phi}_{\underline{p}}1^{\Psi}_{\underline{k}}|T^{(1)}|1^{\Phi}_{\underline{q}}1^{\Psi}_{\underline{l}}\ in\rangle| + |\langle in\ 1^{\Phi}_{\underline{p}}1^{\Phi}_{-\underline{q}}1^{\Psi}_{\underline{k}}|T^{(1)}|1^{\Psi}_{\underline{l}}\ in\rangle|^2\}(1+|\beta_{\underline{p}}|^2) \tag{51}$$

which are related to the diagrams of figure 7

FIGURE 7

Because there is with $|\beta_k|^2 = 0$ no amplification in the massless case, we have $N^{int}(\underline{k}^{\Psi}|\leftarrow)^{(2)} = \{...\}$ with the bracket of (51) and therefore: In Compton scattering, the massive Φ- and the related massless Ψ-particles leaving the mutual interaction are not going out in pairs, as one would expect from the situation in flat space-time. Rather the number of

the massive particles is amplified by a momentum dependent factor according to

$$N^{(2)}(\underline{p}^{\Phi}|\leftarrow) = N^{(2)}(\underline{k}^{\Psi}|\leftarrow)[1+|\beta_{\underline{p}}|^2] \tag{52}$$

Relevance of the σ-term

The example of particle creation out of the vacuum for the expansion law

$$a^2(\eta) = 1 + e^{2b\eta}$$

in the different orders of the mutual interaction

$$L_I = -\frac{\lambda\sqrt{-g}}{a^2(\eta)}\Phi\Psi$$

has been discussed rigorously by Audretsch and Spangehl (1986). The results show that the σ-term of equation (46) dominates the second order. This demonstrates that in higher order the process of gravitationally induced amplification/attenuation is only one effect among others. In general we will not have the pure case

Additional examples for induced amplification and attenuation

Close inspection of results obtained by various authors in other contexts reveals contributions of the effect of amplification/attenuation. This is the case for the discussion of particle creation from vacuum according to the interaction $L_I = \lambda\Phi^4$ by Birrell and Ford (1989), according to the interaction $L_I = L_I(h_{\alpha\beta},\Phi)$ (with $h_{\alpha\beta}$ being an unquantized perturbation of the metric) by Friedmann (1989) and according to the QED-interaction $L_I = ie\,\overline{\Psi}\gamma^{\mu}A_{\mu}\Psi$ by Lotze (1985). The latter is an example for attenuation.

Stimulated emission in zeroth order by black holes and accelerated mirrors

Amplification in zeroth order (no mutual interaction between quantum fields) has also been discussed in detail by Wald (1976). He showed for

Schwarzschild black holes that enormous energies are required for the ingoing particles to induce spontaneous emission at late times. If these energies are bounded, there is only stimulated emission (i.e. amplification) at early times and the usual thermal radiation at late times.

For Kerr black holes the same is true for nonsuperradiant modes. In superradiant modes the effect equals classical superradiant scattering if the number of ingoing particles is large (Wald, 1976). Panangaden and Wald (1977) have shown that the results agree with a formula obtained classically by thermodynamical and information theoretic arguments. Finally we have to mention the stimulated emission by accelerated mirrors as discussed by Davies and Fulling (1977).

TRANSITION PROBABILITIES AND THE TWO TIME SCALES

Example: Decay of a massive particle in the $\Phi\Psi^2$-model

As an application of the concept of the added-up probability introduced above, we discuss the decay of a massive particle with the intention to determine its lifetime in the presence of external cosmological gravitational fields. The inherent conceptual difficulties of an S-matrix approach to questions of this type will thereby become evident.

In order to enable rigorous calculations up to a certain order in the coupling parameter and because we are primarily interested in structural discussion, we use toy expansion laws for which the relevant physical effects become very transparent (Audretsch et. al., 1987). The first expansion law is a step

$$\hat{a}(\eta) = \Theta(-\eta)\, a_i + \Theta(\eta)\, a_o \tag{53}$$

with $a_i = (A-B)^{1/2}$, $a_o = (A+B)^{1/2}$, $A > B > 0$ (see figure 8).

For comparison we then add the corresponding rigorous calculation for the tanh expansion law (see figure 8b)

$$\tilde{a}(\eta) = (A + B \tanh b\eta)^{1/2} \tag{54}$$

which may be regarded as the prototype of a smoothed out step representing an influence of a curved background of finite duration. Both are statically bounded monotonic expansion laws with flat or approximately flat in- and out-regions allowing simple particle definitions. The Bogoliubov coefficient in the step case is simply

$$\hat{\beta}_{\underline{p}} = -(E_o - E_i)/2(E_o E_i)^{1/2} \tag{55}$$

where we have introduced the energy parameter

$$E_{i/o} = (\underline{p}^2 + m^2 a_{i/o}^2)^{1/2} \tag{56}$$

FIGURE 8

We study the decay of one massive into two massless particles according to the mutual interaction

$$L_i = \sqrt{-g}\,(\lambda/a(\eta))\Phi\varphi^2 \tag{57}$$

By including the factor $a(\eta)^{-1}$ the calculations for the rigorous approach are made more simple. The mass of the Φ-particles breaks conformal invariance. There are two in-in diagrams contributing (compare figure 9). The second reflects energy non-conservation, but also the first diagram is to be taken into account outside energy conservation too.

FIGURE 9

After working out the respective transition amplitudes in the step case we obtain for the added-up probability to find two massless Ψ-particles in the out-region if one massive Φ-particle with momentum parameter $\underline{p}$ has been going in:

$$\hat{w}^{add}(1^{\Psi}_{\underline{k}}1^{\Psi}_{\underline{p}-\underline{k}}|1^{\Phi}_{\underline{p}}) = \frac{\lambda^2\pi}{2k|\underline{p}-\underline{k}|V}\left[\frac{1}{2}\frac{1}{E_i}T_\eta\,\delta(\omega_{-i}) + \right.$$
$$\left. + \left(\frac{1}{2}+|\hat{\beta}_{\underline{p}}|^2\right)\frac{1}{E_o}\,T_\eta\,\delta(\omega_{-o})\right] + \hat{\Delta}(k) \tag{58}$$

The momentum parameter is conserved. Because of the asymptotic switching of the mutual interaction according to (7), the infinite conformal time T_η appears. It represents the duration of the interaction between the particles. For the tanh case the result has a similar structure. It is obtained by replacing hat by tilde and by adding a finite correction to the infinite time T_η of the mutual interaction:

$$\tilde{w}^{add} = \hat{w}^{add}(\hat{}\to\tilde{};\ T_\eta \to T_\eta + \text{finite}) \tag{59}$$

The latter will prove to be important below.

The typical k-dependence of the two terms $\Delta(k)$ and $\hat{\Delta}(k)$ is shown in figure 10.

FIGURE 10

These terms as well as the δ-functions become singular at $\omega_{-i} = 0$ and $\omega_{-o} = 0$ defined according to

$$\omega_{-i/o} = E_{i/o} - k - |\underline{k}-\underline{p}| \tag{60}$$

With (56) this means that the decay process becomes resonant when in addition to 3-momentum conservation also the measured energy is conserved. Because the measured energy depends on $a(\eta)$ and we have two asymptotic regions with the different values a_i and a_o, there are two resonances at different values of k. They reflect a sort of minkowskian kernel in the process. Because the cosmological space-time does in fact not demand energy conservation, there is a finite spectrum outside of the resonances.

This is included into the resulting expression when we go over to the <u>total decay probability</u>

$$w^{tot} = \sum_{\underline{k}} w^{add}(|_{\underline{k}}^{\Psi}|_{\underline{p}-\underline{k}}^{\Psi}|\,|_{\underline{p}}^{\Phi}) \tag{61}$$

in summing over all outgoing massless modes. For the step case we find:

$$\hat{w}^{tot} = \frac{\lambda^2}{4\pi m}\left[\frac{1}{2a_i}\, T_\eta + \frac{1}{2a_o}\left(\frac{1}{2} + |\hat{\beta}|^2\, T_\eta\right)\right] \tag{62}$$

This expression refers to a massive particle at rest ($\underline{p} = 0$). Again the result in the tanh case is obtained by replacing hat by tilde and adding a finite term R^{fin}.

$$\tilde{w}^{tot} = \hat{w}^{tot}(\hat{}\to\tilde{}) + R^{fin}(a_i, a_o, |\tilde{\beta}|^2) \tag{63}$$

with $\beta = \beta_{\underline{p}=0}$.

We turn to the interpretation of the two results (62) and (63) and start with a comparison of the step case with the minkowskian total transition probability

$$w^{tot}_{Mink} = \frac{\lambda^2}{4\pi m}\, T_t \tag{64}$$

where the infinite duration T_t of the mutual interaction refers to the measured time t. In the step case one half of the particles has the chance to decay in the Minkowski region $\eta \leq 0$ with $a(\eta) = a_i$ and the other half in the region $\eta \geq 0$ with $a(\eta) = a_o$. This explains the factors 1/2. The parameters a_i and a_o appear in the result, because L_I of (57) contains λ/a instead of λ. Introducing in (64), according to $T_t = a_i\, T_\eta$, the conformal time T_η we obtain the first term of (62).

With regard to the second term in (62) we have to take into account that in addition at $\eta = 0$ massive particles are created out of the vacuum. The creation is according to (19) described by means of $|\beta|^2$. These particles are decaying only in the region $\eta \geq 0$. Therefore, as compared to the first term, the factor 1/2 has to be replaced by $(1/2 + |\beta|^2)$.

For the tanh-case the first term of the result (63) is of exactly the same structure. In this case too, the two nearly static regions are responsible and lead to the factors $1/a_i$ and $1/a_o$ respectively. Again there is a decay of particles created in zeroth order.

But in contrast to the step case, the tanh-case shows a peculiarity: The gravitational influence is not localized to $\eta = 0$ but smeared out over a finite time interval around $\eta = 0$ which we will denote by T^{grav} (gravitational time). This fact is responsible for the appearance of the finite additional term R^{fin} in the result (63).

This latter observation can also be made correspondingly for other expansion laws $a(\eta)$. The following seems to be a general trait of the scheme used above: A gravitational influence of finite duration leads to additive finite corrections of terms which are themselves proportional to the time of the mutual interaction between the particles. This time T_η is infinite because the mutual interaction is switched off according to (7) only asymptotically. The result is that an S-matrix approach to quantum field theory in curved space-time contains inherently two time scales if the influence of the background curvature is of finite duration.

We have to take this into account when going on to the reciprocal <u>lifetime</u> of massive particles at rest. In the minkowskian case this is easily obtained in dividing (64) by T_t:

$$\frac{1}{\tau_{Mink}} = \frac{\lambda^2}{4\pi m} \tag{65}$$

The corresponding procedure gives in the step case

$$\frac{1}{\tau} = \frac{\lambda^2}{4\ m} \left(\frac{1}{2a_i} + \frac{1}{2a_o} \right) + \frac{\lambda}{4\pi E_o} |\beta|^2 \tag{66}$$

In the tanh case on the other hand we have to refer to the two time scales. A natural consequence would be to divide R^{fin} by the finite gravitational time T^{grav}.

$$\frac{1}{\tau} = \frac{\tilde{w}^{tot}}{T_\eta} + \frac{R^{fin}}{T^{grav}} \tag{67}$$

This procedure will at least lead to some physically reasonable mean value for the decay rate. Nevertheless it must be stressed that in general T^{grav} cannot be defined exactly. The development of a satisfying method to work out transition probabilities, which are appropriately localized in time, still remains an open problem.

Other expansion laws

The relations above reflect a general structure for all statically bounded expansion laws. The results for expansion laws with one or two infinite regions are contained as limiting cases, e.g. a_i finite, $a_0 \to \infty$ with ($E_0 \to \infty$), compare Audretsch and Spangehl (1985) for an example.

An example showing the modification of a minkowskian result

A treatment of the particle decay along the lines sketched above for the expansion law

$$a^2(\eta) = a_i^2 + e^{2b\eta}\ ,\ b > 0 \tag{68}$$

has been given by Audretsch and Spangehl (1985). Again the mean value of the local minkowskian result is gravitationally corrected. Figure 11 shows

FIGURE 11

that in this case the gravitational influence dominates for large values of the parameter b. Although this rigorous calculation is based on a toy interaction and an unrealistic expansion law, it demonstrates once more severe restrictions of the local applicability of minkowskian results. This is one of the general lessons to be learned.

Additional examples of worked out transition probabilities

Several calculations of transitions probabilities can be found in the literature. The following effects have been discussed:

- For massless scalar and a Maxwell field

$$L_I = \lambda F_{\mu\nu} F^{\mu\nu} \Psi \tag{69}$$

particle decay from vacuum (Birrell, Davies and Ford, 1980) and particle decay and CPT non-invariance (Lotze, 1987).

- For two massive scalar fields

$$L_I = \lambda R(\Phi^* \Lambda(t) \Psi + \Psi^* \Lambda^*(t) \Phi) \tag{70}$$

particle creation from vacuum (Papastamatiou and Parker, 1979).

- For massive and massless scalar fields

$$L_I = \lambda \Phi \Psi^n \tag{71}$$

particle decay and CPT non-invariance (Ford, 1982).

- For Dirac and Maxwell fields (QED)

$$L_I = ie\bar{\Psi}\gamma^{\mu}A_{\mu}\Psi \tag{72}$$

particle creation from vacuum (Lotze, 1985a,b), emission of a photon by an electron (Lotze, 1988), particle decay and CPT non-invariance (Lotze, 1989).

For self-interacting fields see Birrell and Ford (1979) and Leahy and Unruh (1983).

Accelerated observers, black holes

Finally we have to mention discussions of the Green function. Unruh and Weiss (1984) have shown for several interactions that an accelerated observer in thermal equilibrium measures the same Green function as the Minkowski observer in his vacuum state. A similar result has been obtained for black holes by Gibbons and Perry (1978), see also the exact treatment of the Thirring model by Birrell and Davies (1978).

QUANTUM STRINGS IN CURVED SPACE TIMES

N. SANCHEZ

DEMIRM, Observatoire de Paris, Section de Meudon
92195 Meudon Principal Cédex, France

INTRODUCTION

We discuss string theory in the context of quantum gravity, with specific treatment of string quantization in curved space times. The contents of these lectures is the following. In lecture I we discuss thermal and ground state effects of quantum strings : (i) (first) string quantization in Rindler space-time and its applications to the Scharzschild geometry (ii) the Hawking-Unruh effect in string theory and its description in terms of analytic mappings. In Lecture II we give a new approach to string quantization in curved space time in order to take into account strong curvature effects of the geometry. We apply our method to (i) de-Sitter space-time (ii) the quantum string dynamics and scattering in black hole space times. In lecture III we treat the case of boosted black-holes in the ultra relativist limit (gravitational schock wave or Aichelburg Sexl geometry) in the context of (i) the particle scattering at the Planck energy scale and (ii) quantum string dynamics and scattering in this geometry, (in this case, the problem can be solved exactly).

CONTEXTUAL BACKGROUND

Perhaps the main challenge in theoretical physics today is the unification of all interactions including gravity. At present, string theories appear as the best candidates to achieve such an unification. However, many technical and conceptual problems remain and a quantum theory of gravity is still non available. Continuous effort over the last quarter of a century has demonstrated the many difficulties encountered in repeated attempts to construct such a theory and have also indicated some of the particular properties which an eventual complete theory will have to possess. The amount of work in that direction can be by now presented in two different sets which have most evolved (and remain) separated : (i) conceptual unification (introduction of the uncertainty principle in general relativity, the interpretation problem, Q.F.T. in curved space time and by accelerated observers, Hawking radiation and its consequences, "wave function of the universe"...) (ii) grand unification (the unification of all interactions including gravity from the particle physics point of view. Gravity is considered as a massless spin two particle (the graviton) : supergravities, Kaluza-Klein theories and the more successful superstrings).

Quantum Mechanics in Curved Space-Time
Edited by J. Audretsch and V. de Sabbata
Plenum Press, New York, 1990

Whatever the final theory of the world will be if it is to be a theory of everything, we would like to know what new understanding it theory of everything, we would like to know what new understanding it will give us about the singularities of classical general relativity. If string theory would provide a theory of quantum gravity, it should give us a proper theory (not yet existent) for describing the ultimate state of quantum black holes and the initial (say, very early) state of the Universe. That is, a theory describing the physics (and the geometry) at Planck energies and lengths.

Till now, gravity has not completely been incorporated in string theory : strings are most frequently formulated in a flat space-time. Gravity appears through massless spin two particles (graviton). One disposes only of partial results for strings in curved backgrounds ; these mainly concern the problem of consistency (validity of quantum conformal invariance) through the vanishing of the beta functions. The non-linear quantum string dynamics in curved space-time have only been studied in the slowly-varying approximation for the goemetry (background field method) where the field propagator is essentially taken as the flat space Feynman's propagator. Clearly, such approximations are useless for the study of strings in strong curvature regimes where quantum gravity effects are important. Our aim is to properly understand strings in the context of quantum gravity. As a first step in this program we propose ourselves to study Q.S.T. (Quantum string Theory) in curved spacetimes. (Of course the main goal should be to extract the particle spectrum and the space time itself from string theory but, as it is known, one is very far from doing that explicitely). There are different kind of effects to be considered here : ground state and thermal effects associated to the fact that in General Relativity there are no prefered reference frames, and to the possibility of having different choices of time and curvature effects which as we will see will modify the mass formula, critical dimension and scattering amplitudes of strings. There are also conceptual aspects which appear for instance when strings are restricted to live in a bounded region of the space-time, ie in the presence of event horizons, and which imply quantum fluctuations of the event horizon (and of the light-cone itself).

THERMAL AND GROUND STATE EFFECTS

The formulation of Quantum Field Theory in non trivial (curved or flat) space times has given new fundamental features with respect to the usual understanding of Q.F.T. in trivial (Minkowski flat) space time, i.e. : i) the possibility for a given field theory to have different alternative well defined Focks spaces (different "sectors" of the theory) ; (ii) the presence of "intrinsic" statistical features (temperature, entropy) arising from the non-trivial structure (geometry, topology) of the space time and not from a superimposed statistical description of the quantum matter fields. Relevant examples are Q.F.T. on the Rindler manifold and its analytic mapping extensions (1-2), black-holes and cosmological (de Sitter) space-times.

Quantum field theory developed for curvilinear (accelerated) coordinates in flat space in a way which can be directly generalized to curved space-time is an useful step for a physical and mathematical discussion of the full theory. The genuine coordinate independence which is so familiar in the classical theory of general relativity is not a particular property of gravity but a fundamental principle prevalent in all descriptions of physical laws. On the other hand, the apparent difference which results from the treatment of a quantum field theory in a variety of coordinate systems (in either curved or flat space-time) is not a coordinate effect at all, but is a consequence of the fact that physically different quantum states are correctly described by the quantum theory as being physically distinct. "Canonical" states for different coordinate systems are physically different (each timelike vector field leads to a separate indication of what constitutes a definition of positive frequency).

Strings in Rindler space

Much of the present interest in string theories comes from the hope that they may provide a finite theory of quantum grivity. It seems natural in this context to investigate the quantization of strings in a curved space-time. As a first step in this programme we study the quantization of a string in a uniformly accelerated space (D-dimensional Rindler space). Although this is a flat space-time, it possesses a space-time structure including an event horizon, similar to a black-hole manifold. In order to quantize the string properly in this manifolds, a horizon regularization is needed. This regularization can be introduced through the definition of the Rindler co-ordinates as follows :

$$x_1 \pm x_0 + \varepsilon = e^{\alpha(X^1 \pm X^0)}$$
$$x^i = X^i \quad , \quad i = 2, \ldots, D \qquad (1)$$

where (x^1, x^0) and (X^1, X^0) are respectively Minkowskian (Kruskal-like) and Rindler (Schwarzschild-like) co-ordinates. α is a constant defining the proper acceleration of the Rindler observers (is equal to the surface gravity in the black hole case) and ε is an infinite simal parameter of the order of the Planck length. The horizon is now at a finite distance $|X^1 \pm X^0| \sim 1/\alpha \ln 1/\varepsilon$. This regularization reflects the fact that a classical description of the geometry is no longer valid at distances of the order of the Planck length.

We quantize the string in a light-cone gauge where the light-cone variables are $(x^1 \pm x^0)$ and $(X^1 \pm X^0)$. This choice is particularly convenient here since the acceleration points in the x^1 direction. We recall that for Q.F.T. in accelerated frames (in flat and curved space-times), different time-like vector fields lead to inequivalent positive frequency modes 1)-3). In the light cone gauge, positive frequency modes with respect to the time-like variable (τ) on the string world sheet are physical states when is identified with the appropriate time variable in the physical space-time. We associate inertial and accelerated particle states of the string to positive frequency modes with respect to x^0 and X^0 respectively. We find that the accelerated frequencies of the accelerated modes differ in a large factor.

$$\lambda_0 = \frac{2\pi\alpha}{\ln\left(\frac{2\pi}{\varepsilon} + 1\right)} \quad , \qquad (2)$$

from the inertial ones. Physically this factor reflects the indefinite increasing of the string length when it approaches the event horizon. We develop the string dynamics in Rindler space and write the corresponding constraints. The longitudinal co-ordinates X^0 and X^1 obey non linear equations of motion but, as in the inertial case, they can be eliminated in terms of the transverse co-ordinates which are the independent dynamical variables. Two possible situations appear depending on whether the centre of mass has a uniform speed or a uniform acceleration. The mass formulae are derived in each case. The Poincaré invariance of the flat Minkowski space-time has a non-linear realization in terms of the Rindler co-ordinates. We prove that the passage from the inertial to accelerated modes of the string is a canonical transformation both at the classical and quantum levels. We also check that an explicit realization of the Poincaré algebra can be constructed in terms of the accelerated modes, provided (at the quantum level) one sets D = 26 and uses symmetric ordering of the operators. The explicit expression of the Bogoliubov coefficients relating the inertial and Rindler modes of the string is found. The expectation value of the Rindler number mode operator in the ground state (tachyon) of the string is computed. This follows a thermal distribution [Eq. (62)] with temperature

$$T_s = \frac{\alpha}{2\pi} \qquad (3)$$

This is the same Hawking-Unruh value that appears in the fiel-theoretical context. However, if one measures the frequency in dimensionless units (1,2,....) instead of multiples of λ_0 (eq. (2)), the temperature of the ground state is a (very large) pure number

$$T_0 = \frac{T_s}{\lambda_0} = \frac{1}{4\pi^2} \ln\left(\frac{2\pi}{\varepsilon} + 1\right)$$

we find the expectation value of the accelerated mass M'operator in the (tachyon) ground state ; it turns out to be a large positive number

$$M' = 2\pi T_0 \qquad (5)$$

The major features of the string quantization in Rindler space also holds for a string in a Schwarzschild space-time. An appropriate light-cone gauge can be introduced for left or right movers in the null Kruskal and Schwarzschild co-ordinates. Now, Eq. (2) for λ_0 gives the relation between the Kruskal and Schwarzschild frequencies and T_S and T_0 Eqs. (3)-(4) give the temperatures characterising the ground state of the string in the black hole manifold with

$$\varepsilon \sim \left(\frac{M_{Pl}}{M}\right)^{(D-2)/(D-3)} \quad , \qquad \alpha \equiv K \sim \left(\frac{M_{Pl}}{M}\right)^{\frac{D-2}{D-3}}$$

Here Mpl and M stand for the Planck mass and the blak hole mass respectively. It can be noticed that the Hagedorn temperature in this context ($1/\sqrt{\alpha'} \sim M_{Pl}$)is always $\gtrsim$ Ts $\sim$ Mpl $(Mpl/M)^{1/(D-3)}$ since a basic requirement for the present semiclassical treatment is M $\gtrsim$ Mpl. The investigations presented here can also be extended to the case of fermionic strings and to more general (non uniform) accelerations described by analytic (holomorphic) mappings as in the approach of Ref.2).

<u>Horizon regularization in Rindler-space - Introduction of the ε parameter</u>

Let us discuss now some features of Rindler space which are important for our study of strings in this space. The Rindler transformation maps the right-hand wedge $x^1 \geq |x^0|$ of Minkowski space onto the whole Rindler space $-\infty < X^1, X^0 < \infty$ the whole Minkowski space can be covered using four different Rindler patches. As is known, a quantum field in Rindler space is in a thermal state with temperature $T = \alpha/(2\pi)$. In addition, ultra-violet divergences arise in the free energy and entropy of quantum fields from the existence of a horizon at $x^1 = |x^0|$, ($X^1 = -\infty$)in the space-time. The same problem appears in the case of a four-dimensional black hole. Let us illustrate this phenomenon by considering a free massive scalar field . In D-dimensional Rindler space, the positive frequency modes are

$$\Psi = \frac{1}{(2\pi)^{(D-2)/2}} e^{i(-\lambda X^0 + k^i X^i)} \Phi(X^1), \quad \lambda > 0, \quad k^i \in \mathbb{R} \qquad (6)$$

where $\Phi(X^1)$ satisfies

$$\left[\frac{d^2}{dX^{1\,2}} + \lambda^2 - (m^2 + k^{i\,2})\alpha^2 e^{2\alpha X^1}\right] \Phi(X^1) = 0$$

the total number $\mathcal{N}_\lambda$ of wave modes with fequency less than λ can be computed in the semi-classical approximation for $\lambda \gtrsim \alpha$. This is enough to study the ultra-violet behaviour of the quantities interesting us. In the W.K.B. approximation $\mathcal{N}_\lambda$ is given by

$$\pi \mathcal{N}_\lambda = \int_{-H}^{a(\lambda)} dX^1 \int \prod_{i=1}^{D-2} \frac{dk^i}{2\pi} \sqrt{\lambda^2 - (m^2 + k^{i\,2})\alpha^2 e^{2\alpha X^1}} \qquad (7)$$

The integration is taken over the values of K^i and X^1 for which the argument of the square root is positive. Here a (λ) is the classical turning point

$$e^{\alpha a(\lambda)} = \lambda / m\alpha \quad ,$$

and H is a large cut-off ($H \gtrsim 1/\alpha$) on the negative Rindler co-ordinate X^1. This shifts the horizon by replacing the light-cone $x^1 - |x_0|$ as a boundary of Rindler space-time by the hyperbola

$$(x^1)^2 - (x^0)^2 = e^{-2\alpha H} \tag{8}$$

This regularization takes into account the fact that a classical description of the geometry is no longer valid at distances of order of the Planck length. Thus,

$$e^{-2\alpha H} \sim \ell_{Pl}$$

Evaluating $\mathcal{N}_\lambda$ for large H it yields

$$\pi \mathcal{N}'_\lambda = \frac{1}{4} \frac{(\lambda/\alpha)^{D-1}}{(4\pi)^{(D-3)/2}\,(D-2)} e^{\alpha H (D-2)} \left[1 + O(e^{-2\alpha H}) \right] \tag{9}$$

Then the free energy and the entropy at temperature T :

$$F = - \int_0^\infty \mathcal{N}_\lambda \, d\lambda \, (e^{\lambda/T} - 1)^{-1} \quad , \qquad S = - \partial F / \partial T \, ,$$

are equal to

$$F = - \frac{\Gamma(D)\, \zeta(D)\, T}{(4\pi)^{(D-1)/2}\,(D-2)} \alpha^{1-D} e^{\alpha H (D-2)} \tag{10}$$

$$S = - D F / T \qquad > 0$$

In Rindler space, $T = \alpha / 2\pi$ and so

$$F = - \Gamma(D)\, \zeta(D)\, \alpha \, (4\pi)^{1/2 - D} \pi^{-D} e^{\alpha H (D-2)} \tag{11}$$

$$S = \Gamma(D)\, \zeta(D)\, 2\pi D \, (4\pi)^{1/2 - D} \pi^{-D} 2\pi D \, e^{\alpha H (D-2)}$$

We explicitly see that F and S need the ultra-violet cut-off H to be finite. This is equivalent to considering the following mapping defining the accelerated co-ordinates

$$x^1 - x^0 + \varepsilon = e^{\alpha (X^1 - X^0)}$$
$$x^1 + x^0 + \varepsilon = e^{\alpha (X^1 + X^0)} \tag{13}$$

where $\varepsilon \simeq e^{-\alpha H}$, $-H \leq X^1 \leq +\infty$.

<u>Analytic mappings and the Hawking Unruh effect in String Theory</u>

As it is known, the string action in a D-dimensional (generically curved) space-time is given by

$$S = \frac{1}{2\pi\alpha'} \int d\sigma d\tau \sqrt{g}\, g^{\alpha\beta} G_{AB}(X)\, \partial_\alpha X^A \partial_\beta X^B \tag{14}$$

$G_{AB}(X)$ and $g_{\alpha\beta}(\sigma,\tau)$ stand for the space-time and the world-sheet metrics respectively, namely

$$ds^2 = G_{AB}(X)\, dX^A dX^B \quad , \quad 0 \leq A, B \leq D-1 \tag{15}$$

$(2\pi\alpha')^{-1}$ is the string tension (we will take here $\alpha' = 1$).

The equations of motion and the constraints are

$$\Box^2 X^A + \Gamma^A_{BC}(X)\, \partial_\alpha X^B \partial_\beta X^C g^{\alpha\beta} = 0 \qquad (16)$$

$$T_{\alpha\beta} = G_{AB}\, \partial_\alpha X^A \partial_\beta X^B - \frac{1}{2} g_{\alpha\beta}\, \partial_\sigma X^A \partial^\sigma X^B = 0 \qquad (17)$$

$\Gamma^A_{BC}(X)$ stand for the Christoffel connections of the metric G_{AB}. As is well known, the action (14) is invariant under reparametrizations of the world-sheet co-ordinates

$$\delta X^\mu = \varepsilon^\alpha(\xi)\, \partial_\alpha X^\mu(\xi) \quad , \quad \xi^\alpha = (\sigma, \tau)$$

under which the two-dimensional metric $g_{\alpha\beta}$ goes to

$$\delta g_{\alpha\beta}(\xi) = \varepsilon^\gamma \partial_\gamma g_{\alpha\beta} + (\partial_\alpha \varepsilon^\alpha) g_{\gamma\beta} + (\partial_\beta \varepsilon^\gamma) g_{\alpha\beta}.$$

This reparametrization invariance allows us to choose $g_{\alpha\beta}$ in the conformal form (so called "conformal gauge"), namely,

$$\begin{aligned} g_{\alpha\beta} &= \Lambda(\xi)\, \eta_{\alpha\beta} \,, \\ ds^2 &= \Lambda(\sigma,\tau)\,(d\sigma^2 - d\tau^2) \end{aligned} \qquad (18)$$

The choice of the conformal gauge still allows the reparametrizations

$$\begin{aligned} x_+ + \varepsilon &= f(x'_+ + \ell) \\ x_- + \varepsilon &= g(x'_- + \ell) \end{aligned} \qquad (19)$$

(where $x_\pm = \sigma \pm \tau$, $x'_\pm = \sigma' \pm \tau'$ and we have introduced the constants ε, ℓ whose meaning will be clear in the sequel). In this way, we can choose the light-cone gauge:

$$V \equiv X_0 + X_1 = p_+ x_+ \qquad (20)$$

where the proportionality constant $p_+ > 0$ is the momentum of the centre-of-mass of the string.

An important step in field as well as string quantization is the definition of positive frequency states and its associated ground state. It is by now well known, in QFT (in either flat or curved

space-times) that "canonical states" for different co-ordinate systems are physically different (each timelike vector field leads to a separate indication of what constitutes a positive frequency)[1),2)]. There are different ways (and there is thus an ambiguity) in choosing such a basis. This makes it possible for a given field theory to have different alternative well-defined Fock spaces (different "sectors" of the theory). To illustrate this feature in string theory, let us consider the simplest case $G_{AB} = \eta_{AB}$, i.e.,

$$dS^2 = -dX^{0\,2} + dX^{1\,2} + \ldots\ldots + dX^{D-1\,2} , \qquad (21)$$

which means both that the space-time is flat and that the string is described in an inertial frame. Usually the string is described in this frame where

$$\partial_{x_+} \partial_{x_-} X^A = 0 \quad , \qquad A = 0, 1, \ldots, D-1 \qquad (22)$$

and then positive frequency modes are defined with respect to the inertial time X^0. In the light-cone gauge, X^0 is proportional to τ and therefore the modes

$$\overleftarrow{\varphi}_n = \frac{1}{2\sqrt{\pi|n|}} e^{-inx_+} \quad , \quad \overrightarrow{\varphi}_n = \frac{1}{2\sqrt{\pi|n|}} e^{inx_-} \qquad (23)$$

define the (inertial) particle states of the string.

Obviously, if we consider the (σ',τ') parametrization of the string world sheet [Eq. (19)], i.e.,

$$\sigma' + \ell = \frac{1}{2}\left[G(\sigma+\tau+\varepsilon) + F(\sigma-\tau+\varepsilon)\right] , \quad F \equiv f^{-1}$$
$$\tau' = \frac{1}{2}\left[G(\sigma+\tau+\varepsilon) - F(\sigma-\tau+\varepsilon)\right] , \quad G \equiv g^{-1} \qquad (24)$$

for which we have

$$\partial_{x'_+} \partial_{x'_-} X^A = 0 \quad , \qquad (25)$$

positive frequency modes with respect to τ', namely

$$\overleftarrow{\phi}_n = \frac{1}{2\sqrt{\pi|n|}} e^{-i\lambda_n x'_+} \quad , \quad \overrightarrow{\phi}_n = \frac{1}{2\sqrt{\pi|n|}} e^{i\lambda_n x'_-} \qquad (26)$$

do not define positive frequency modes with respect to X^*, i.e., are not inertial particle states of the string. However, they are positive frequency modes with respect to another (accelerated) time $X^{*\prime}$ defined by

$$\begin{aligned} X_1 - X_0 &= p_- f\,(X_1' - X_0') \\ X_1 + X_0 &= p_+ g\,(X_1' + X_0') \end{aligned} \tag{27}$$

where f is the same as in Eq. (19). This corresponds to the description of the string in an accelerated reference frame $\{X_0', X_1', \ldots, X_{D-1}'\}$, with acceleration

$$\tilde{a} = \frac{1}{[f'g']^{1/2}} \; \partial_{X_1'} \left[\ln (f'g') \right]$$

and metric

$$dS^2 = p_+ p_- f'(X_1' - X_0')\, g'(X_1' + X_0') \left[-dX_0'^{\,2} + dX_1'^{\,2} \right] + dX_2'^{\,2} + \cdots + dX_{D-1}'^{\,2} \tag{28}$$

where, for simplicity, we have taken

$$X_i' = X_i \qquad , \quad (i = 2, \ldots, D-1)$$

For the description of the string in this frame we can always choose

$$V \equiv X_1' + X_0' = x_+' + \ell \tag{29}$$

as it follows from Eqs. (19), (20) and (27). Thus, Eq. (25) defines the accelerated particle states of the string. [The choice (29) is particularly useful here because of the acceleration points in the X^1 direction]. In this frame, the equations of motion of the string are

$$\partial_{x_+'} \partial_{x_-'} U' + \frac{f''}{f'} \partial_{x_+'} U' \partial_{x_-'} U' + \left(\frac{f''}{f'} - \frac{g''}{g'} \right) \partial_{x_+'} U' \partial_{x_-'} V' = 0 \tag{30}$$

$$\partial_{x_+'} \partial_{x_-'} V' + \frac{g''}{g'} \partial_{x_+'} V' \partial_{x_-'} V' - \left(\frac{f''}{f'} - \frac{g''}{g'} \right) \partial_{x_+'} U' \partial_{x_-'} V' = 0$$

$$\partial_{x_+'} \partial_{x_-'} X'^{i} = 0 \tag{31}$$

The equations of motion of the physical (transverse degrees) of freedom are the same in both frames. The equations of motion of the longitudinal co-ordinates (U',V') are different, but it can be shown[3] that, as in the inertial case[4], they can be eliminated in terms of the transverse co-ordinates by using the constraints

$$T^{1}_{\pm\pm} = f'(U')\, g'(V')\, \partial_{\pm'} U\, \partial_{\pm'} V + \partial_{\pm'} X^{i}\, \partial_{\pm'} X^{i} \approx 0$$
$$T^{1}_{+-} = 0 \tag{32}$$

The Poincaré invariance of flat space-time has a non-linear realization in terms of the accelerated co-ordinates, but an explicit realization of the Poincaré algebra can be constructed in terms of the accelerated modes provided (at the quantum level) one sets D = 26 and uses symmetric ordering of the operators[3].

The manifold (σ',τ') defined by Eq. (24) is the convenient world sheet parametrization for an accelerated string or a string in an accelerated space-time. This is true in either flat or curved space-time [although in the last case, Eq. (25) can only be valid asymptotically for $x^{1}_{\pm} \to \pm\infty$].

Let us describe the string in the reference frames (21) and (28) referred in the sequel as (I) and (A) respectively. We consider here a closed string and take for simplicity f ≡ g. The boundary conditions are

$$X^{\mu}(0,\tau) = X^{\mu}(\pi,\tau)$$
$$X^{\mu}(0,\tau') = X^{\mu}(L_{\varepsilon},\tau') \tag{33}$$

Notice that

$$0 < \sigma < \pi \qquad\qquad -\infty < X^{0} < +\infty \;.$$
$$-\infty < \tau < +\infty \tag{34}$$

In order to have

$$0 < \sigma' < L_{\varepsilon} \qquad\qquad -\infty < X'^{0} < +\infty \,,$$
$$-\infty < \tau' < +\infty \tag{35}$$

appropriate boundary conditions on the mappings must be imposed. Condition (33) is automatically satisfied from Eqs. (19) with

$$L_\varepsilon = F(\varepsilon + 2\pi) - F(\varepsilon) \qquad F \equiv f^{-1}$$
$$\ell = F(\varepsilon) \qquad , \qquad (36)$$

Condition (35) on τ' and X'^* is not particular to strings. It is required to get a consistent quantization (of fields or strings) in accelerated manifolds and to have a complete in (out) basis[2]. On the other hand, the manifold A can cover only a (bounded) region (namely $|X^1| > |X^*|$) of the original (I) one. Similarly, the manifold (σ',τ') can cover only a domain ($|\sigma| > \tau$) of the inertial or global world sheet. All these considerations are satisfied by taking mappings such that

$$u_\pm = f(\pm\infty) \quad , \qquad (37)$$

where $u_+(u_-)$ are constants which can take independently finite or infinite values and $u_+ > u_-$. This means that the inverse mapping $F \equiv f^{-1}$ has singularities at $u = u_\pm$, i.e.,

$$F(u_\pm) = \pm\infty \qquad (38)$$

Singularities of these mappings describe the asymptotic regions of the space-time. Critical points of f, i.e.,

$$f'(\pm\infty) = 0 \qquad (39)$$

describe event horizons at $u = u_-$ and $u = u_+$. In this case $u_-(u_+)$ are finite and the manifold A cover the region $u_- < |X^1 \pm X^*| < u_-$ of the global (I) space-time. If $u_\pm = \pm\infty$, there are no horizons. In this approach, the well-known Rindler's space corresponds to the mapping

$$f = e^{\alpha U'} \qquad , \quad \alpha = \text{const.} \qquad (40)$$

In this case, $u_- = 0$ and $u_+ = +\infty$; $u = u_- = 0$ is an event horizon and the manifold covers the right-hand wedge $|U| > 0$. (In order to cover the whole plane, four Rindler's patches are needed.) For the string world sheet we have

$$x_\pm + \varepsilon = e^{\alpha(x'_\pm + \ell)} \qquad (41)$$

and we see how the presence of the constant ε is necessary in order to have a finite string period in the manifold (σ',τ'). For the Rindler's mapping (41) we have

$$\ell = \frac{1}{\alpha} \log \varepsilon$$
$$L_\varepsilon = \frac{1}{\alpha} \log \left(\frac{2\pi}{\varepsilon} + 1 \right) \tag{42}$$

For $\varepsilon \to 0$, there is a stretching effect of the string due to the presence of an event horizon in the world sheet.

Let us now consider the string quantization in the frames (I) and (A). The string co-ordinates can be split into left and right movers as

$$X^A(\xi) = \overleftarrow{X}^A(\xi_+) + \overrightarrow{X}^A(\xi_-) \tag{43}$$

where $\xi_\pm$ stands for $\sigma \pm \tau$ or $\sigma' \pm \tau'$. As usual, left and right modes of the closed string decouple both in the classical and quantum theories. We consider first the left movers. The wave modes are periodic functions of x_+ and x_- with period 2π. The left modes which are only functions of x_+ will be periodic functions of $x_+' = \sigma' + \tau'$ with period L_ε. In the inertial frame (I) we have

$$\overleftarrow{X}^i(x_+) = \frac{q^i}{2} + \frac{p^i}{2} x_+ + \frac{1}{2} \sum_{n \neq 0} \frac{\overleftarrow{a}_n^i}{\sqrt{|n|}} e^{-inx_+}$$

$$\overleftarrow{U}(x_+) = q_- + p_- x_+ + \frac{i}{2} \sum_{n \neq 0} \frac{\overleftarrow{\mu}_n}{n} e^{-inx_+} \tag{44}$$

$$p_- = \frac{\mu_0}{2}$$

The independent dynamical variables $\overleftarrow{a}_n^i (n \in z)$, q_i, q_+ and p_+ obey the canonical commutation relations

$$[\overleftarrow{\alpha}_n^i, \overleftarrow{\alpha}_m^j] = n\,\delta_{n+m}\,\delta^{ij}, \quad \overleftarrow{\alpha}_n^i = -i\sqrt{|n|}\,\mathrm{sgn}\,\overleftarrow{a}_n^i, \; n \neq 0$$
$$[q^i, \overleftarrow{\alpha}_0^j] = i\,\delta^{ij}, \quad \overleftarrow{\alpha}_0^i = p^i \tag{45}$$
$$[q_-, p_-] = i$$

Then

$$[\overleftarrow{X}^i(x_+), \overleftarrow{p}^i(y_+)] = \frac{\delta^{ij}}{2} \delta(x_+ - y_+)$$

The energy-momentum tensor, the conformal generators and the mass operator are

$$T_{++}(x_+) = \sum_{n\in\mathbb{Z}} \frac{L_n}{2\pi} e^{-in x_+} ,$$

$$L_n = \frac{1}{2}\sum_m \overleftarrow{\alpha}_m^i \overleftarrow{\alpha}_{n-m}^i + p_+ \overleftarrow{u}_n \tag{46}$$

$$L_0 = \frac{1}{2}\sum_m \overleftarrow{\alpha}_m^i \overleftarrow{\alpha}_{-m}^i + 2 p_+ p_-$$

and

$$M^2 = p_+ p_- - p_i^2 = \sum_n \frac{n}{2}\left(a_n^{i+} a_n^i + a_n^i a_n^{i+}\right)$$

$$= \sum_n n\, a_n^{i+} a_n^i - \frac{(D-2)}{24} \tag{47}$$

In the accelerated frame (A) we have

$$\overleftarrow{X}^i(x'_+) = \frac{Q^i}{2} + \frac{P^i}{2} x'_+ + \sum_{n\neq 0} \overleftarrow{C}_n^i \overleftarrow{\Phi}_n(x'_+)$$

$$\overleftarrow{U}(x'_+) = u_0 + \frac{P_-}{2} x'_+ + \frac{i}{2}\sum_{n\neq 0} \frac{\gamma_n}{n} e^{-i\lambda_n x'_+} \tag{48}$$

with

$$\overleftarrow{X}(x'_+ + L_\varepsilon) - \overleftarrow{X}(x'_+) = \frac{P^i}{2\pi} L_\varepsilon$$

$$\overleftarrow{U}(x'_+ + L_\varepsilon) - \overleftarrow{U}(x'_+) = \frac{P_-}{2} L_\varepsilon \tag{49}$$

and

$$P^i = \frac{2\pi}{L_\varepsilon} p_i \quad , \quad P_- = \frac{2\pi}{L_\varepsilon} p_-$$

The left modes provide the T'_{++} component of the energy-momentum tensor. The accelerated conformal generators (L'_n) follow from the Fourier transform of T'_{++}:

$$T'_{++}(x'_+) = \sum_{-\infty}^{\infty} \frac{L'_n}{L_\varepsilon} e^{-i\lambda_n x'_+}$$

$$L'_n = L'^{\perp}_n + L'^{\parallel}_n \approx 0 \tag{50}$$

$$L_n^{\prime\perp} = -\frac{1}{L_\varepsilon} \sum_m \overleftarrow{\beta}_m^{\,i}\, \overleftarrow{\beta}_{n-m}^{\,i}$$

$$\overleftarrow{C}_n^{\,i\,+} = i\,\mathrm{sgn}\, \overleftarrow{\beta}_n^{\,i}/\sqrt{|n|} \quad , \quad \overleftarrow{\beta}_n^{\,i} = \overleftarrow{\beta}_{-n}^{\,i} \quad , \quad \beta_0 = p^i, \quad \gamma_0 = p_- .$$

We find the following Fock representation

$$\begin{aligned} [\overleftarrow{C}_n^{\,i}, \overleftarrow{C}_m^{\,j}] &= \delta_{nm}\, \delta^{ij} \quad , \quad [\overleftarrow{\beta}_n^{\,i}, \overleftarrow{\beta}_m^{\,j}] = n\,\delta^{ij}\delta_{n+m,0} \\ [P^i, Q_0^{\,j}] &= -\left(\frac{2\pi}{L_\varepsilon}\right) i\, \delta^{ij} \\ [p_+, u_0] &= -i \end{aligned} \tag{51}$$

which implies

$$[\overleftarrow{X}^i(\xi), \overleftarrow{P}^j(\xi')] = \frac{i}{2}\, \delta(\xi-\xi')\, \delta^{ij} \tag{52}$$

For a string whose centre-of-mass follows an accelerated world line in the longitudinal direction X^1, of the type

$$x^1 \pm x^0 \pm a_\pm = A_\pm\, e^{\pm\alpha\tau'} \quad , \quad a_\pm, A_\pm = \text{const.}$$

it is convenient to use the expansion[3)]

$$U = U_0 + \frac{1}{f(x'_+)} \left[\tilde{p}_- + \frac{i}{2} \sum_{n\neq 0} r_n\, e^{-i\lambda_n x'_+} \right] \tag{53}$$

for which the mass formula is given by

$$\begin{aligned} M'^2 = (\alpha\, L_\varepsilon)^2 p_+ \tilde{p}_- - p_i^{\,2} &= \sum_1 \frac{n}{2} \left(C_n^{i\,+} C_n^{\,i} + C_n^{\,i} C_n^{i\,+} \right) \\ &= \sum_1 n\, C_n^{i\,+} C_n^{\,i} - \frac{(D-2)}{24} \end{aligned} \tag{54}$$

The operators M^2 and M'^2 [Eqs. (47) and (54)] are different but both have the same eigenvalues.

The same treatment applies to the right movers $\vec{X}^A$ in a gauge defined by

$$\vec{U}^1 = p_- x_-$$

and with $\vec{U}^1 = x'_- + \ell$,

$$\text{ie} \quad x_- + \varepsilon = f(x'_- + \ell)$$

The (I) and (A) Fock representations are related by a Bogoliubov transformation

$$C_m^i = p^i O_m + \sum_{n=1}^{\infty} \left(A_{mn} a_n^i + B_{mn} a_n^{i+} \right), \quad m \neq 0 \tag{55}$$

with Bogoliubov coefficients

$$A_{mn} = \langle \phi_{\lambda m}, \varphi_n \rangle = \frac{1}{2\pi} \sqrt{\frac{n}{m}} \int_0^{2\pi} e^{in\sigma - i\lambda_m F(\sigma+\varepsilon)} d\sigma$$

$$B_{mn} = \langle \phi_{\lambda m}, \varphi_n^* \rangle = \frac{1}{2\pi} \sqrt{\frac{n}{m}} \int_0^{2\pi} e^{in\sigma + i\lambda_m F(\sigma+\varepsilon)} d\sigma \tag{56}$$

and zero-mode contribution

$$O_m = \left\langle \frac{1}{2} \left(x_+ - \frac{2\pi}{L_\varepsilon} x'_+ \right), \phi_{\lambda m} \right\rangle$$

The ground state of the string is defined by

$$\begin{aligned} a_n^i |0\rangle &= 0 \\ p^i |0\rangle &= 0 \end{aligned} \qquad \forall n > 1 \tag{57}$$

We also have

$$\begin{aligned} C_m |0'\rangle &= 0 \\ P^i |0'\rangle &= 0 \end{aligned} \qquad \forall m > 1 \tag{58}$$

but $C_m|0\rangle \neq 0$. The expectation value of the accelerated number operator in the ground state $|0\rangle$ is equal to (not sum over i)

$$N^i(\lambda_m) \equiv \langle 0 | C_m^i C_m^{i+} | 0 \rangle = N(\lambda_m) = \sum_{n=1}^{\infty} |B_{mn}|^2 \tag{59}$$

which is i-independent. The expectation value of the accelerated M'^2 operator is equal to

$$M'^2 = 24 \sum_1^{\infty} n N(n) - 1 \tag{60}$$

where N(n) is given by Eq. (59) with $\lambda_n = (2\pi/L_\varepsilon)n$. If $f(x'_+ + \ell) = e^{\alpha(x'_+ + \ell)}$, then:

$$B_{mn}(n \gg 1) = \mathcal{C}(\lambda_m)\,\frac{n^{-i\lambda_m/\alpha}}{\sqrt{n}} + \frac{b}{\sqrt{n}} + O\left(\frac{1}{n^{3/2}}\right)$$

$$\mathcal{C} = \frac{i}{2\pi}\,\frac{e^{-\frac{\pi\lambda_m}{2\alpha}}}{\sqrt{m}}\,\Gamma\left(1 + \frac{i\lambda_m}{\alpha}\right), \tag{61}$$

$$b = -\frac{i}{2\pi}\left(\frac{2\pi}{\sqrt{m}}\right)^{i\lambda_m/\alpha}$$

and

$$N(\lambda_m) = \frac{1}{\left(e^{2\pi\lambda_m/\alpha} - 1\right)} + \frac{\alpha}{2\pi\lambda_m} \tag{62}$$

$$M'^2 = 24\left[\sum_{n=1}^{\infty}\frac{n}{\left(e^{n/T_0} - 1\right)} + T_0\right] - 1$$

$$M'^2_{\varepsilon \ll 1} = \frac{1}{2\pi}\ln\frac{2\pi}{\varepsilon} \tag{63}$$

[Recall that in field theory, $B_{\lambda k}(k \gg 1) = \mathcal{C}(\lambda)\,(k/\sqrt{k})^{-i\lambda/\alpha}$, with $\lambda \in R$.] $N(\lambda_n)$ [Eq. (62)] is equal to a Planckian spectrum at the Hawking-Unruh temperature

$$T_s = \frac{\alpha}{2\pi} \tag{64}$$

In $N(n)$, the temperature is

$$T_0 = \left(\frac{L_\varepsilon}{2\pi}\right) T_s = \frac{a}{2\pi} \underset{\varepsilon \ll 1}{=} \frac{1}{(2\pi)^2}\ln\left(\frac{2\pi}{\varepsilon}\right) \tag{65}$$

The expectation value of M'^2 in the ground state $|0\rangle$ is <u>positive</u>. The tachyon level of this state is filled up with accelerated modes following a thermal distribution. For any other mapping f different from the exponential one [Eq. (41)], $B_{nm}(n \gg 1) \to e^{-n}$ and $N(\lambda_n)$ and $N(n)$ are non-thermal.

It can be noted that the acceleration as well as the temperature T_s appearing in $N(n)$ are re-scaled by the factor $(L_\varepsilon/2\pi)$, i.e., the ratio of the string period in the inertial and in the accelerated frame. Thus, the dimensionless temperature T_0 does not depend on the acceleration parameter α of Rindler's space, but on the parameter

$$a = \left(\frac{L_\varepsilon}{2\pi}\right)\alpha = \frac{1}{2\pi}\ln\left(\frac{2\pi}{\varepsilon} + 1\right) \underset{\varepsilon \ll 1}{=} -\frac{\ell\alpha}{2\pi} \tag{66}$$

We see that the parameter ε $[\ell \equiv \ell(\varepsilon)]$ introduced in the mappings on the world sheet, plays a fundamental rôle in the string context. ε acts as a regulator or cut-off to avoid the presence of an event horizon in the world sheet and to get a finite string period. Its magnitude is of the order of the Planck length.

TRANSFORMATION BETWEEN THE STATES: DERIVATION OF THE PARAMETER ε FROM THE CONSTRAINT EQUATIONS

We see that the transformations (19) are not without consequences but change the ground state and in general, the quantum states, except for mappings belonging to the O(2,1) group. Such invariance mappings are the Möbius or bilinear transformations. Under the transformations (19) and (27), the states transform as

$$| \rangle \rightarrow | ' \rangle = e^{i \hat{G}'} | \rangle \tag{67}$$

where $a_n | \rangle = 0$, $C_n | ' \rangle = 0$, $\forall_n$ and

$$\hat{G} = \sum_n \theta_n \left(C_n C_n - C_n^+ C_n^+ \right)$$

[this is an operatorial representation for the Bogoliubov transformation, Eq. (55), with Bogoliubov coefficients $\cosh\theta_n$ and $\sinh\theta_n$].

The vacuum expectation value of $T_{\mu\nu}$ transforms as

$$\langle T_{\mu\nu} \rangle = \langle T_{\mu\nu}' \rangle + \Theta_{\mu\nu} + P_{\mu\nu} \tag{68}$$

$P_{\mu\nu}$ is any conserved traceless tensor taking into account the dependence of $\langle T_{\mu\nu} \rangle$ on the quantum state. It represents the non-local part of $T_{\mu\nu}$. $\Theta_{\mu\nu}$ depends on the mapping and represents the local part. In the conformal gauge we have

$$P_{--} = \mathcal{U}_-(x'_-) \quad , \quad P_{++} = \mathcal{U}_+(x'_+) \; , \; P_{+-} = P_{-+(69)} = 0$$

$$\Theta_{--} = -\frac{1}{12\pi} \sqrt{f'} \, d^2_{x'_-} \left(\frac{1}{\sqrt{f'}} \right)$$

$$\Theta_{++} = -\frac{1}{12\pi}\sqrt{g'}\, d^2_{x'_+}\left(\frac{1}{\sqrt{g'}}\right) \tag{70}$$

$$\Theta_{+-} = \Theta_{-+} = 0$$

$\mathcal{U}_-$ and $\mathcal{U}_+$ are arbitrary functions of the indicated variables. Equations (69) derive from the conditions $\nabla^\nu P_{\mu\nu} = 0$ and $P_\nu{}^\nu = 0$. Therefore, the constraints

$$\langle T_{\mu\nu} \rangle = 0 \qquad , \qquad \langle T_{\mu\nu}{}' \rangle = 0$$

yield to the equations[5)]

$$\sqrt{f'}\, d^2_{x'_-}\left(\frac{1}{\sqrt{f'}}\right) - 12\pi\, \mathcal{U}_-(x'_-) = 0 \tag{71}$$

$$\sqrt{g'}\, d^2_{x'_+}\left(\frac{1}{\sqrt{g'}}\right) - 12\pi\, \mathcal{U}_+(x'_+) = 0$$

These are zero-energy Schrödinger equations

$$\frac{d^2}{dx'_\pm}\psi_\pm - 12\pi\, \mathcal{U}_\pm(x'_\pm)\,\psi_\pm = 0 \tag{72}$$

for the mappings f and g. By giving the potentials $\mathcal{U}_\pm$, Eqs. (72) determine the wave functions

$$\psi_- = \frac{1}{\sqrt{f'}} \qquad\qquad \psi_+ = \frac{1}{\sqrt{g'}} \tag{73}$$

Because $\mathcal{U}_\pm$ are arbitrary functions [compatible with the boundary conditions (37)], Eqs. (72) do not yield additional constraints on the mappings f and g, but a way of connecting the mapping to a potential problem.

The first term of Eq. (71) is the Schwarzian derivative of f:

$$D[f] = \frac{f'''}{f'} - \frac{3}{2}\left(\frac{f''}{f'}\right)^2 , \tag{74}$$

which is invariant under the Möbius or bilinear transformations. Under these transformations, f becomes a new function but D[f] is invariant determining the same ground state, of the string. In particular, $\mathcal{U}_+ = \mathcal{U}_- = 0$ determine f(g) as

$$f = \frac{\alpha x'_- + \beta}{\gamma x'_- + \delta} \quad , \quad (\alpha\delta - \beta\gamma) = 1 \qquad (75)$$

The ground state defined by this mapping can be considered as a reference or "minimal" state at zero temperature with respect to which other ground states corresponding to non-zero potentials $\mathcal{U}_\pm$ appear as excited or thermal ones. If $\mathcal{U}_+ = \mathcal{U}_- = \mathcal{U}_0$ = constant > 0, then

$$\psi_\pm = A\, e^{-K x'_\pm} \quad , \quad f = \frac{1}{\alpha A^2}\, e^{\alpha x'_+} - \varepsilon \qquad (76)$$

where A is a normalizing constant (we choose $A^2 = e^{-\alpha\ell}/\alpha$) and K is the zero-energy transmission coefficient

$$K \equiv \frac{\alpha}{2} = \sqrt{12\pi\,\mathcal{U}_0} \quad ,$$

For $\varepsilon \to 0$, the mapping (76) defines an event horizon at $x_\pm = 0$ ($x'_\pm = -\infty$) and carries an intrinsic temperature $T_s = \alpha/2\pi$, as can be seen by putting $t = i\tau$ ($x_+ = x + i\tau$) and then $0 \leq \tau' \leq 2\pi/\alpha$. The temperature appears related to the height of the potential, namely

$$T_s = \sqrt{\frac{12\,\mathcal{U}_0}{\pi}}$$

and the parameter ε arises naturally as an integration constant. This temperature T_s characterizes the spectrum $N(\lambda_n)$, Eq. (62).

Similar equations to (71) also appear in the so-called "back reaction problem" in two dimensions[6] [as a consequence of the (±±) components of the semi-classical Einstein equations, the (+-) component giving rise to the Liouville equation for the geometry because of the conformal anomaly]. Equations (71) can also be derived in the context of conformal field theories on higher genus Riemann surfaces (the potential playing the rôle of the zero-point energy) in connection with the approach of Ref. 7).

We have shown that with appropriate boundary conditions, the holomorphic mappings of reparametrization invariance of string theory can be interpreted as a change of co-ordinate frame in the space-time in which strings are embedded. These mappings change the ground state in the quantized theory except for transformations belonging to the O(2,1) group. This allowed us to discuss in a systematic way the Hawking-Unruh effect in string theory. The transformations describing

the world sheet of an accelerated string need the introduction of an additional parameter ε with respect to those describing the trajectories of accelerated point particles.

The results found here apply also to curved space-time. For the most important metrics in general relativity, the presence of isometry groups allows the maximal analytic extension of the (D-dimensional) manifold to be performed through the extension of a relevant two-dimensional manifold containing the time axis and a suitable spatial co-ordinate. This maximal analytic extension is performed by mappings like [Eq. (27)], where X_1, X_0 are Kruskal (maximal) type co-ordinates and X_1', X_0' are of the Schwarzschild type. [For the role played by these mappings in the context of Q.F.T., see Refs. 8) and 9).]

STRINGS NEAR BLACK HOLES

Our investigation of strings in Rindler space-time can be applied to the case of strings in a black hole background. Black hole solutions of Einstein equations exist in D-space-time dimensions (D > 4)[10]. These solutions are asymptotically flat and generalize the Schwarzschild space-time of four dimensions; they have the metric

$$dS^2 = -\left(1 - \frac{C}{R^{D-3}}\right) dT^2 + \frac{dR^2}{\left(1 - \frac{C}{R^{D-3}}\right)} + R^2 d\Omega^2_{D-2} \tag{77}$$

R is the radial co-ordinate, $d\Omega^2_D$ is the line element on the unit D-sphere and the constant C is > 0. The surface

$$R = C^{1/D-3} \equiv R_S$$

is an event horizon (there are both past and future event horizons) and R = 0 is a space-like singularity. The horizon radius R_S is related to the black hole mass M by

$$C = 16\pi G \frac{M}{(D-2)\, A_{D-2}}$$

where

$$A_{D-2} = \frac{2\pi^{(D-1)/2}}{\Gamma\left(\frac{D-1}{2}\right)}$$

is the area of a unit (D-2) sphere and G has dimensions of length^{D-2}.

The mass and the surface gravity K of the black hole are related by

$$K = \left(\frac{D-3}{2R_s}\right) = \frac{(D-3)}{2}\left[\frac{(D-2)\,A_{D-2}}{16\pi G M}\right]^{\frac{1}{D-3}} \tag{78}$$

For D = 4 this yields the standard relations $R_S = 2GM$ and $K = 1/(4GM)$.

The Kruskal extension of this Schwarzschild manifold is given by the mapping

$$r_K \pm t_K = e^{K(R^* \pm T)} \tag{79}$$

where

$$R^* = R + R_s^{D-3}\int\frac{dR}{(R^{D-3} - R_s^{D-3})}$$

$$-\infty \leq R^*, T \leq +\infty \quad .$$

This is the same exponential mapping as the Rindler transform with K instead of α. The Rindler co-ordinates are similar to the Schwarzschild (R^*, T) ones and the Minkowskian co-ordinates are similar to the Kruskal (global) co-ordinates (r_K, t_K). The event horizon $R = R_S$ corresponds to $R^* = -\infty$. As discussed above, a large cut-off ($H \gtrsim 1/K$) is needed in the negative Schwarzschild co-ordinate R^*. This shifting of the horizon is equivalent to considering a shifting ε in the mapping

$$r_K \pm t_K + \varepsilon = e^{K(R^* \pm T)} \tag{80}$$

with

$$\varepsilon = e^{-KH} \sim \ell_p^{\,2}$$

and thus

$$-H \leq R^* \leq +\infty$$

reflecting the fact that a classical description of the geometry is no longer valid at distances of order of the Planck length. We will take

$$\varepsilon = \frac{\lambda_c}{R_S}, \qquad \text{where} \qquad \lambda_c = \frac{1}{M}$$

is the Compton length of the black hole (here $\hbar = c = 1$). Thus the shifting of the horizon is $H = (1/K) \ln\varepsilon$, with

$$\varepsilon = \pi^{1/2} \left[\frac{(D-2)}{8\,\Gamma\left(\frac{D-1}{2}\right)} \right]^{\frac{1}{D-3}} \left(\frac{M_{Pl}}{M} \right)^{\frac{D-2}{D-3}} \tag{81}$$

and

$$K = \frac{\pi^{1/2}}{2} (D-3) \left[\frac{(D-2)}{8\,\Gamma\left(\frac{D-1}{2}\right)} \right] \left(\frac{M_{Pl}}{M} \right)^{\frac{1}{D-3}} M_{Pl} \tag{82}$$

Following on the same lines of argument discussed above, for the choice of gauge and parametrizations of the string world sheet and considering only left movers, we have

$$\overleftarrow{v} \equiv r_K + t_K = p_+ x_+ \tag{83}$$

$$V \equiv R^* + T = x'_+ + \frac{1}{K} \log p_+ \tag{84}$$

and

$$x_+ + \varepsilon = e^{K x'_+}$$

(Here the longitudinal direction of the string is in the radial direction.)

Positive frequency modes, $\overleftarrow{\varphi}_n$ with respect to the Kruskal time t_K and $\overleftarrow{\phi}_n$ with respect to the Schwarzschild time T can be defined. The Schwarzschild frequency is equal to

$$\lambda_n = \frac{2\pi}{L_\varepsilon} n, \qquad n = 1, 2, \ldots \tag{85}$$

where $$L_\varepsilon = \frac{1}{K} \ln \left(\frac{2\pi}{\varepsilon} + 1 \right)$$

For $\varepsilon \ll 1$, the frequency spacing tends to zero reflecting the stretching effect of the string near the horizon as seen by a Schwarzschild external observer. Associated to the modes $\overleftarrow{\psi}_n$ and $\overleftarrow{\phi}_n$ we will have Kruskal and Schwarzschild operators a_n and C_n respectively and a vacuum state defined by

$$a_n \, | 0_K \rangle = 0 \, , \qquad \forall n > 1$$

On the other hand, in order to have a smooth Euclidean manifold from a black hole space-time with topology $R^2 \times S^{D-2}$, the Schwarzschild imaginary time iT must be identified with a period

$$\beta = \frac{2\pi}{K}$$

Then the same periodicity in the imaginary time appears in the correlation functions of string co-ordinates, indicating that the string is in equilibrium with a heat bath at the Hawking temperature

$$T_s = \frac{K}{2\pi} \tag{86}$$

The same temperature T is recovered in the function $N(\lambda_m)$, i.e.,

$$N(\lambda_n) = \langle 0_K | \, C_{\lambda n}^{+} \, C_{\lambda n} \, | 0_K \rangle \, ,$$

which gives a Planckian distribution for the Schwarzschild modes but with a "filter" $|g(\lambda_n)|^2$ equal to the absorption cross-section of the black hole. In the spectrum N(n) in which frequency is measured in dimensionless units 1,2,..., the temperature of the Planckian distribution is equal to

$$T_0 = \frac{1}{4\pi^2} \ln \left(\frac{2\pi}{\varepsilon} \right) \gg 1 \tag{87}$$

One can consider different higher dimensional black hole space-times, namely a 26-dimensional or a four-dimensional black hole with the extra 22 dimensions compactified in a torus[11]. Intermediary situations can also be envisaged but it must be noticed that the qualitative properties of the string quantization will be the same

since they depend upon the horizon structure in the two variables R, T (or X^0, X^1, for Rindler space). We hope to come back to this problem elsewhere.

It can be noticed that the Hagedorn temperature (T_m) in this context is

$$T_m = \frac{1}{\sqrt{\alpha'}} \sim M_{pl}$$

Then,

$$\frac{T_s}{T_m} \sim \left(\frac{M_{pl}}{M}\right)^{\frac{1}{D-3}}$$

and we have

$$T_s \lesssim T_m$$

since the basic requirement of the present semiclassical treatment is $M \gtrsim M_{pl}$.

NEW APPROACH TO STRING QUANTIZATION IN CURVED SPACE-TIMES

The main feature of strings propagating in a curved space-time is that the equations of motion [Eq. (16)] are non-linear in X_A, so right and left movers interact with each other and also with themselves. It must be noticed that purely left modes (or right modes) are exact solutions of Eq. (16), namely

$$X_A = q_A(\sigma+\tau) \qquad \text{or} \qquad X_A = q_A(\sigma-\tau) \tag{88}$$

When G_{AB} is the metric of a symmetric space, the equations of motion possess an associated linear system and exact solutions can be constructed, by using the inverse scattering method. In Ref. 12), we propose a general perturbative scheme to solve the equations of motion and constraints both classically and quantum mechanically. We start from an exact given solution of Eqs. (16) and develop in perturbations around. A possible starting point is a solution for the centre-of-mass motion of the string $q_A(\tau)$ where

$$\ddot{q}^A(\tau) + \Gamma^A_{BC}(q)\,\dot{q}^B(\tau)\,\dot{q}^C(\tau) = 0 \qquad (89)$$

The world-sheet time variable τ is identified here with the proper time of the centre-of-mass trajectory. Another possibility is to take pure left(right) mover solutions. Then we set

$$X_A(\sigma,\tau) = q_A(\sigma,\tau) + \eta_A(\sigma,\tau) + \xi_A(\sigma,\tau) + \cdots \qquad (90)$$

Here $q_A(\sigma,\tau)$ is an exact solution of Eq. (16) and η_A is a solution of the linearized perturbation around q_A. That is

$$\partial^2\eta^A + \Gamma^A_{BC}(q)\left(\partial_- q^B \partial_+ + \partial_+ q^B \partial_-\right)\eta^C + \partial_C \Gamma^A_{BD}(q)\,\partial_+ q^B \partial_- q^D \eta^C = 0 \qquad (91)$$

$\xi_A(\sigma,\tau)$ fulfil the second order perturbation equation around q_A:

$$\begin{aligned}\partial^2\xi^A &+ \Gamma^A_{BC}\,\partial_+\eta^B\,\partial_-\eta^C + \frac{1}{2}\eta^D\eta^E\left(\partial^2_{DE}\Gamma^A_{BC}\right)\partial_+ q^B\,\partial_- q^C + \\ &+ \eta^D\left(\partial_D\Gamma^A_{BC}\right)\left(\partial_+ q^B\partial_- + \partial_- q^B\partial_+\right)\eta^C + \\ &+ \Gamma^A_{BC}\left(\partial_+ q^B\partial_- + \partial_- q^B\partial_+\right)\xi^C + \left(\partial_D\Gamma^A_{BC}\right)\partial_+ q^B\,\partial_- q^C\,\xi^D = 0\end{aligned} \qquad (92)$$

One can consider the higher-order perturbations but in this note we will restrict ourselves to first and second orders.

It must be noticed that we are treating the space-time metric <u>exactly</u> and taking the string oscillations around its centre-of-mass $q_A(\tau)$ as perturbation. So, our expansion corresponds to low excitations of the string, as compared with the energy scales of the metric G_{AB}. For example, this method is exact in flat space-time. In the Schwarzschild geometry, it will correspond to an expansion in ω/M where ω is the frequency mode and M the black hole mass. Thus, our approximation applies to black hole masses larger than the string energy. In other words, this corresponds to a strong gravitational field expansion. This can be equivalently considered as an expansion in powers of $\sqrt{\alpha'}$. Actually, since $\alpha' = \ell^2_{p\ell}$, ($\ell_{p\ell}$ is the Planck length), the expansion parameter turns out to be the dimensionless constant

$$g \equiv \sqrt{\pi}\,\frac{\ell_p}{R_c} = \frac{1}{\ell_p M} \simeq \frac{\omega}{M} ,$$

where the length R_c characterizes the curvature radius of the space-time under consideration and M its associated mass (the black hole mass in the Schwarzschild geometry, the mass of the Universe in a cosmological model). In most of the interesting situations, one clearly has $g \ll 1$.

It must be noticed that even for small g, the metric and its derivatives may be very large in some regions of the space-time. This shows that our method has a <u>larger domain of applicability</u> than the background field method where one must have everywhere

$$\left| \sqrt{\alpha'}\ \partial_c G_{AB}(x) \right| \ll 1 .$$

The first order equation describes the interaction between the string modes and the curved space-time geometry. The interactions between the string modes themselves start to appear from the second order perturbation (ξ^A) equation.

The constraint equations must also be expanded in perturbations. We find up to terms higher than the second order:

$$\begin{aligned} T_{\pm\pm} = {} & G_{AB}(q)\,\partial_\pm q^A \partial_\pm q^B + 2 G_{AB}\,\partial_\pm q^A \partial_\pm \eta^B + \\ & + \eta^c \partial_c G_{AB}(q)\,\partial_\pm q^A \partial_\pm q^B + \frac{1}{2}\eta^c \eta^D \partial_{cD} G_{AB}(q)\,\partial_\pm q^A \partial_\pm q^B + \\ & + 2\eta^c \partial_c G_{AB}(q)\,\partial_\pm q^A \partial_\pm \eta^B + \xi^c \partial_c G_{AB}(q)\,\partial_\pm q^A \partial_\pm q^B + \\ & + 2 G_{AB}(q)\,\partial_\pm q^A \partial_\pm \xi^B + G_{AB}(q)\,\partial_\pm \eta^A \partial_\pm \eta^B \simeq 0 . \end{aligned} \tag{93}$$

See Ref. 12) where we have applied our method to the case in which the exact solution q_A describes the centre-of-mass motion.

This defines the Ln generators as

$$T_{\pm\pm} = \frac{1}{2\pi} \sum_{n \in \mathbb{Z}} L_n\, e^{in(\sigma \pm \tau)} \tag{94}$$

In this second order approximation the constant operators Ln are bilinear in the fields η^A. One must solve the linear equation (92) for ξ^A expressing them as a bilinear functional of η^A. Inserting this expression for ξ^A in Eq. (93) give the generator Ln as operators bilinear in the η^A. Closed solutions of ξ^A, η^A andLn are given below for the de Sitter universe.

Let us now consider the case where the exact solution describes the centre of mass motion. It fulfils besides Eq. (89)

$$m^2 = G_{AB}(q)\, \dot{q}^A(\tau)\, \dot{q}^B(\tau) \tag{95}$$

This defines the (mass)2 of the string. The fluctuation equation (9) and (10) simplify in this case. One can expand in Fourier series

$$\eta^A(\sigma,\tau) = \sum_{n\in Z} e^{in\sigma}\, C_n^A(\tau) \tag{96}$$

and the C_n^A satisfy <u>decoupled</u> ordinary differential equations

$$\ddot{C}_n^A + m^2 C_n^A + 2\,\Gamma^A_{BC}(q)\,\dot{q}^B \dot{C}_n^C + \dot{q}^B \dot{q}^C\, \partial_C \Gamma^A_{BD}(q)\, C_n^D = 0 \tag{97}$$

In this case, the constraint equation read to second order :

$$\begin{aligned} T_{\pm\pm} = {} & m^2 \pm 2\, G_{AB}\, \dot{q}^A (\partial_\pm \eta^B + \partial_\pm \xi^B) + G_{AB}\, \partial_\pm \eta^A \partial_\pm \eta^B + \\ & + (\eta^C + \xi^C)\, \partial_C G_{AB}(q)\, \dot{q}^A \dot{q}^B + \frac{1}{2}\eta^C \eta^D\, \partial_{CD} G_{AB}(q)\, \dot{q}^A \dot{q}^B + \\ & + 2\, \partial_C G_{AB}(q)\, \eta^C \dot{q}^A\, \partial_\pm \eta^B \simeq 0 \end{aligned} \tag{98}$$

here ξ^A is to be expressed in terms of the η^A through the solution of the linear equation (10). This procedure can be iterated to higher orders. One has only to solve <u>ordinary linear</u> differential equations at any step.

Non-physical degrees of freedom are to be eliminated by imposing the constraints (Eq. (98). In addition, the mass spectrum follows from the component of these constraints. it must be noticed that one must use the solution of the equation of motion of second order (ξ^A) in order to construct physically interesting $T_{\pm\pm}$. It is easy to check that this $T_{\pm\pm}$ is conserved order by order in the perturbation expansion. This perturbative scheme can be consistently extended to any order of perturbation and around any exact solution of the equations of motion.

<u>Quantum strings in de Sitter space-time</u>

As a first application of this general method we considered the de Sitter space-time. It is defined by the metric

$$ds^2 = \left(\frac{R_0}{X^0}\right)^2 \left[(dX^0)^2 - (dX^i)^2 \right], \quad 1 \le i \le D-1 \tag{99}$$

Here $R_0 = H^{-1} = 3/\sqrt{\Lambda}$ and the curvature scalar $R = HD\,(D-1)$ is constant. In this case the center of mass motion (eq. (89) admits the solution

$$\begin{aligned} & q^0(\tau) = \frac{gm}{p\,\sinh(gm\tau)} \qquad q^1(\tau) = r^1 - \frac{gm}{p}\coth(gm\tau) \\ & q^i(\tau) = r^i \quad , \quad 2 \le i \le D-1 \quad , \quad p^2 = \sum_{i=1}^{D-1} p_i^2 \end{aligned} \tag{100}$$

Here r^i and p^i are constants ($1 \le i \le D-1$) and we choose the X^1-axis in the direction of the motion.

The first order perturbation equations (91) read in this case

$$\partial^2\eta^0 + \frac{2}{q^0}(\dot q^0\dot\eta^0 + \dot q^1\dot\eta^1) - [(\dot q^0)^2 + (\dot q^1)^2]\,\eta^0/(q^0)^2 = 0$$

$$\partial^2\eta^1 + \frac{2}{q^0}(\dot q^0\dot\eta^1 + \dot q^1\dot\eta^0) - 2\dot q^0\dot q^1\eta^0/(q^0)^2 = 0$$

$$\partial^2\eta^i + 2\dot q^0\dot\eta^i/q^2 = 0 \quad , \quad 2 \leq i \leq D-1 \tag{101}$$

This set of equations can be solved exactly in closed form (12). The general solution is

$$\eta^0(\sigma,\tau) = \frac{1}{p\sinh^2(mg\tau)}\left[A_1(\sigma,\tau) + B(\sigma,\tau)\cosh(mg\tau)\right]$$

$$\eta^1(\sigma,\tau) = -\frac{1}{p\sinh^2(mg\tau)}\left[B(\sigma,\tau) + A_1(\sigma,\tau)\cosh(mg\tau)\right]$$

$$\eta^i(\sigma,\tau) = \frac{A_i(\sigma,\tau)}{p\sinh(mg\tau)} \quad , \quad 2 \leq i \leq D-1 \tag{102}$$

Where A_α and B fulfil the free field equations

$$(\partial_\tau^2 - \partial_\sigma^2)\,B(\sigma,\tau) = 0$$

$$(\partial_\tau^2 - \partial_\sigma^2 - m^2g^2)\,A_\alpha(\sigma,\tau) = 0 \quad , \quad 1 \leq \alpha \leq D-1 \tag{103}$$

Therefore, they admit the Fourier expansions

$$A_\alpha(\sigma,\tau) = \sum_{n\in\mathbb{Z}}\left[\gamma_n^\alpha e^{i(n\sigma-\omega_n\tau)} + \gamma_n^{\alpha+} e^{-i(n\sigma-\omega_n\tau)}\right]$$

$$B(\sigma,\tau) = \sum_{n\in\mathbb{Z}}\left[\beta_n e^{in(\sigma-\tau)} + \tilde\beta_n e^{-in(\sigma+\tau)}\right] \tag{104}$$

$$\beta_n = \beta_{-n}^+ \quad , \quad \tilde\beta_n^+ = \tilde\beta_{-n} \quad , \quad \omega_n \equiv \sqrt{n^2 - m^2g^2}$$

The existence of imaginary frequencies for

$$|n| < gm \tag{105}$$

exhibits an instability of de Sitter geometry under the presence of strings. As it is shown in ref. (12) eqs. (102) - (104) define a canonical representation of the commutation rules provided we impose

$$[\gamma_n^\alpha, \gamma_\ell^{\beta+}] = \frac{m^2g^2}{4\pi\omega_n}\,\delta_{n\ell}\,\delta^{\alpha\beta}$$

$$[\beta_n, \beta_\ell] = \frac{m^2g^2}{4\pi n}\,\delta_{n+\ell,0} \tag{106}$$

In summary we can solve all constraints (up to this order) by the gauge choice (12)

$$B(\sigma,\tau) = \alpha m\tau \tag{107}$$

where α is a constant. Furthermore all zero modes can be and must be discarted since they just represent deformations of the centre of mass solution (100). Finally the $L_0 \simeq 0$ constraint yields the mass spectrum. This is no more a linear one. We find (12).

$$\frac{\pi}{2}m^2 = (D-1)\,\mathcal{E}(m^2) + \sum_{n\neq 0}\Omega_n(m^2)\sum_{\alpha=1}^{D-1} a_n^{\alpha+}a_n^\alpha + O(g^2)$$

where

$$\Omega_n(m^2) = \sqrt{n^2 - m^2g^2} + \frac{m^2g^2}{2\sqrt{n^2-m^2g^2}} \tag{108}$$

$$\mathcal{E}(m^2) = \sum_{n=1}^{\infty}\Omega_n(m^2) \tag{109}$$

and

$$a_n^\alpha = 2\sqrt{\pi\omega_n}\,\gamma_n^\alpha/(mg) \quad , \quad [a_n^\alpha, a_\ell^{\beta+}] = \delta_{n\ell}\,\delta^{\alpha\beta} \tag{110}$$

There are (D-1) physical string excitations for each n ($\neq 0$) all of them associated with positive norm states in the Fock space. Recall that in

flat space-time one has (D-2) components. Eqs (109)-(110) permit to obtain the mass spectrum in powers of g. Besides the tachyon scalar particle associated to the ground state, we find two quanta states with mass

$$m^2 = -\frac{D-1}{12} + 2 + O(g^2) \tag{111}$$

Therefore (almost) massless spin-two and zero particles appear at D= 25 They can be identified with the graviton and the dilaton respectively. It is a general feature of de Sitter space-time to lower the critical dimensions in one unit. It must be remarked that the zero-point fluctuation energy (109) is finite upon regularizing the sum.

In addition, we found that the Regge trajectories deviate significatively from linear ones. Moreover we find that only states with $m^2 \lesssim 0$ (1) and spin $\lesssim 49/g2$ are stable at tree level. Beyond these values the particle masses become complex. Therefore, one does not need to go to the one-handle level to find a width for these states. We refer to more details to ref. (12).

Quantum string dynamics and scattering in black-hole space-times

We study the bosonic string in a Schwarzschild geometry. The D-dimensional generalization of the Schwarzschild metric is given by

$$ds^2 = -\left[1-\left(\frac{R_s}{R}\right)^{D-3}\right](dX^0)^2 + \frac{dR^2}{\left[1-\left(\frac{R_s}{R}\right)^{D-3}\right]} + R^2 d\Omega_{D-2} \tag{112}$$

Here R is the radial coordinate. $d\Omega_D^2$ is the line element of the unit D-sphere and the Schwarzschild radius R=Rs defines the event horizon surface

$$R_s = \left[\frac{16\,GM}{(D-2)\,A_{D-2}}\right]^{1/(D-3)}, \quad A_D = \frac{2\pi^{(D+1)/2}}{\Gamma((D+1)/2)} \tag{113}$$

The gravitational constant G has dimensions of (length) $^{D-2}$

The string equations of motion read in this geometry

$$\partial^2 X^0 + \frac{K}{a(R)}\left(R_s/R\right)^{D-2}\partial_\mu X^0\,\partial^\mu R = 0$$

$$\partial^2 R - \frac{K}{a(R)}\left(R_s/R\right)^{D-2}(\partial_\mu R)^2 - a\left[R(\partial_\mu\Omega^i)^2 - K\left(\frac{R_s}{R}\right)^{D-2}(\partial X^0)^2\right] = 0$$

$$\partial^2\Omega^i + \frac{2}{R}\partial^\mu R\,\partial_\mu\Omega^i - \Omega^i(\Omega^j\partial^2\Omega^j) = 0$$

here

$$(\Omega^i)^2 = 1, \quad 1 \le i \le D-2, \quad a \equiv 1-\left(\frac{R_s}{R}\right)^{D-3} \tag{114}$$

$$K = \frac{D-3}{2R_s}$$

The constraint equations write here

$$T_{\pm\pm} = \frac{1}{a}(\partial_\pm R)^2 - a(\partial_\pm X^0)^2 + R^2(\partial_\pm\Omega^i)^2 \simeq 0 \tag{115}$$

Following our general method we set

$$X^A(\sigma,\tau) = q^A(\tau) + \eta^A(\sigma,\tau) + \xi^A(\sigma,\tau) + \cdots \tag{116}$$

where $q^A(\tau)$ obeys the center of mass equation (89). That is

$$m^2 + \frac{1}{\alpha'^2 a}(\dot{q}^R)^2 - \frac{E^2}{a^2} + \frac{L^2}{q_R^2} = 0 \tag{117}$$

where E is the energy and L the angular momentum. Eq. (117) describes the motion in the plane defined by the spherical coordinates $\theta^i = \pi/2$. That is to an angular motion only in the azimutal angle φ. We have

$$q^1 = \cos\varphi \qquad q^2 = \sin\varphi \qquad q^a = 0, \quad a > 2$$

and

$$\dot{\varphi} = \frac{\alpha' L}{q_R^{\,2}} \tag{118}$$

Eqs. (117)-(118) are solvable by quadratures

$$\tau = \int^{q_R} \frac{ds}{\sqrt{E^2 - a(s)(m^2 + L^2/s^2)}} \tag{119}$$

We recognize here an effective potential

$$V_{eff}(q) = \left(m^2 + \frac{L^2}{q^2}\right)\left[1 - \left(\frac{R_s}{q}\right)^{D-3}\right] \tag{120}$$

depending on the initial energy and momentum the particle will be absorbed or elastically scattered by the black-hole.

The first order fluctuations $\eta^A(\sigma,\tau)$ obey here the equations :

$$\begin{aligned} &\partial^2\eta^* + \left[\frac{a'}{2a^2}\left(\dot{q}^{R\,2} + \alpha'^2 E^2\right) - \frac{L^2\alpha'^2}{(q^R)^4}\right] a\eta^* + \\ &+ \frac{a'}{a}\left(\dot{q}^R \dot{\eta}^* + \alpha' E \dot{\eta}^0\right) - 2\dot{q}^R \dot{q}^i \dot{\eta}^i = 0 \\ &\partial^2\eta^i - 2\frac{\dot{q}^i}{q^R}\dot{\eta}^i - 2\dot{q}^i\,\partial_\tau\left(\frac{a\eta^*}{q^R}\right) - \frac{L^2\alpha'^2\eta^i}{(q^R)^4} - 2\dot{q}^i\dot{q}^j\dot{\eta}^j = 0 \end{aligned} \tag{121}$$

Here we use the R* coordinate defined by

$$R^* = R + R_s^{\,D-3}\int^R \frac{dR'}{R'^{D-3} - R_s^{\,D-3}} \tag{122}$$

Eqs. (121) can be easily solved in the asymptotic region $\tau \to \pm\infty$. There, the center of mass is very far from the center of forces and the space-time is practically flat. We set

$$\eta^A(\sigma,\tau) = \frac{\alpha^A(\sigma,\tau)}{q^R(\tau)} \tag{123}$$

and we expand

$$\alpha^A(\sigma,\tau) = \sqrt{\alpha'}\sum_{n\in\mathbb{Z}}\sum_{B=0}^{D-1}\frac{f^{A,B}_{n,\pm}(\tau)}{n}\left\{\alpha^B_{n,\pm}\,e^{-in\sigma} + \tilde{\alpha}^B_{n,\pm}\,e^{in\sigma}\right\} \tag{124}$$

here the functions $f^A_{n,\pm}(\tau)$ fulfil the fluctuation equations (121) with the boundary conditions

$$\lim_{\tau\to\pm\infty} f^{A,B}_{n,\pm}(\tau) = e^{-in\tau}\,\delta_{AB} \tag{125}$$

The choice of a positive frequency factor $e^{-in\tau}$ in eq. (125) corresponds to "in" or "out" particles states for $\tau \longrightarrow -\infty$ or $\tau \longrightarrow +\infty$ respectively. Since we have free oscillators in both asymptotic limits, we get

$$\lim_{\tau\to\mp\infty} f^{A,B}_{n,\pm}(\tau) = A^{A,B}_{n,\pm}\,e^{-in\tau} + B^{A,B}_{n,\pm}\,e^{in\tau} \tag{126}$$

where the constant coefficients $A^{A,B}_{n,\pm}$ and $B^{A,B}_{n,\pm}$ depend on the detailed form of the eqs. (121) for all τ. As a consequence of eqs. (124)-(126) we find that outgoing and ingoing operator modes are related by the Bogoliubov transformation

$$\alpha^{A}_{n,+} = \sum_{B} \left(A^{A,B}_{n,+} \; \alpha^{B}_{n,-} + B^{A,B}_{n+} \; \tilde{\alpha}^{B}_{-n,-} \right)$$
$$\tilde{\alpha}^{A}_{n,+} = \sum_{B} \left(A^{A,B}_{n,+} \; \tilde{\alpha}^{B}_{n,-} + B^{A,B}_{n,+} \; \alpha^{B}_{-n,-} \right) \qquad (127)$$

We see two main effects in the transitions between the string modes produced by the black-hole :

a) Polarization changes in the modes (without changing their left or right character)

b) Pair mode creation. Each pair formed by modes of opposite chirality.

For the modes orthogonal to the scattering plane, we find (13,14)

$$B^{ij}_{n,+} = \delta^{ij} \; B_{n,+} \quad , \qquad 2 < i,j \leq D-1 \qquad (128)$$

Therefore, we find for the pair creation amplitude

$$\langle \overleftarrow{n}_{out} , \overrightarrow{n}_{out} \mid 0_{in} \rangle = B_{n,+} \qquad (129)$$

where $|\overleftarrow{n}_{out}, \overrightarrow{n}_{out}\rangle$ stands for an outgoing state with the left and right n^{th} modes occupied. For an excited initial state, we find

$$\langle \overrightarrow{m}_{out} , \overleftarrow{n}_{out} , \overrightarrow{n}_{out} \mid \overrightarrow{\ell}_{in} \rangle = \delta_{m\ell} \; B_n , \qquad \ell \neq n$$

The coefficients An and Bn have been derived in ref. (14) for large impact parameters explicitely. We found for b>>Rs

$$A_n \underset{b \gg R_s}{=} i\alpha' \left(\frac{R_s}{b}\right)^{D-3} \frac{p\sqrt{\pi}}{b} \; \Gamma\left(\frac{D}{2}+1\right) \left[1 + \frac{D-1}{D} \frac{m^2}{p^2} \right]$$
$$B_n \; b \gg R_s = p\alpha' \left(R_s^{D-3} / b^{D-2} \right) F\left(m/p , nb/\alpha' p \right) \qquad (130)$$

where the function (F(x,y) is defined in ref (14) as a double integral. It must be noticed that Bn is appreciable different from zero when the characteristic interaction time is of the same order of magnitude as the vibration time of the mode. That is

$$\frac{b}{\alpha' p} \simeq \frac{2\pi}{n} \qquad \text{or} \qquad n \simeq \frac{\alpha' p}{b} \qquad (131)$$

when $n \gg \alpha' p/b$, Bn is very small (see eq.130)

The string black hole cross section is computed in ref (14) following our method.

At zeroth order we find for the center of mass cross section

$$\left(\frac{d\sigma}{d\Omega}\right)_{cm} = \left(\frac{b}{\sin\theta}\right)^{D-3} \frac{db}{d\theta}_{\theta \to 0} = \frac{\left[4GM \, \Gamma\left(\frac{D}{2}-1\right) \pi^{2-D/2} \left(1 + \frac{D-3}{D-2} \frac{m^2}{p^2} \right) \right]^{\frac{D-2}{D-3}}}{(D-3) \quad \theta^{D-1+1/D-3}} \qquad (132)$$

This generalizes the Rutherford formula valid for D = 4. Taking into account the first quantum correction yields

$$\left(\frac{d\sigma}{d\Omega}\right)_{elastic} = \left(\frac{d\sigma}{d\Omega}\right)_{cm} \left[1 - \sum_{n' \neq n} |B_{n'}|^2 \right] \qquad (133)$$

By elastic cross section we mean when both the initial state and the final state are the nth mode. The inelastic cross section is proportional to Bn^2.

In conclusion our method allows to explicitely compute physical quantities for strings in curved space-time in powers of ℓ_{pl}/Ro (Ro = characteristic radius of the geometry). This is possible even for singular

metrics. Our method is more powerful than the background field method that only provides explicitely the renormalization constants and beta functions.

Although we have limited ourselves to bosonic strings, fermionic strings can be treated analogously. In addition one can also treat curved space-times where some dimensions have been compactified.

III - PARTICLE AND STRING SCATTERING AT THE PLANCK ENERGY SCALE AND THE AICHELBURG-SEXL GEOMETRY

In order to improve our present (still fragmentary) understanding of quantum gravity, physical insights at the energies of the Planck scale need to be explored (be that in a theory of fields or strings). When the curvature associated to the space time geometry is too strong, the usual description of particle fields or strings in flat space time is no longer valid, the dynamics of the quantum fields (or strings) are governed by their equations of motion in the classical background geometry. Relevant examples are the Hawking effect and the description of quantum fields in curved space times , string quantization in curved space times and more recently 15 the particle scattering in the Aichelburg-Sexl (AS) geometry. As stressed in ref. 15, the AS metric 16 is relevant to the particle scattering at high energy $(s \gtrsim m_{pl}^2)$. In this paper we investigate the quantum dynamics and scattering of a closed string in the AS geometry. This describes the following physical process : the scattering of a string (or one of its possible particle states) by a particle with energy of the order or larger than the Planck mass (m_{pl}). At this energy scale it is necessary to take into account the gravitational field created by such highly energetic particle according the General Relativity. (This is also true even when the rest mass of the particle is small as compared with $m_{pl} = 10^{-5}$ gr). The gravitational field of an ultrarelativistic (neutral and spinless) particle is precisely described by the AS geometry. The motion of the particle is taken here along the x-axis with speed + 1. The interpretation of the AS geometry as a schock wave has been considered in ref (17). We give the D-dimensional generalization of this metric (this generalization has also been given recently in ref. (18). The string is considered here as a test string, that is its energy is much smaller than the energy associated to the AS space time. A general feature of strings propagating in curved space time is that the equations of motion are non-linear, so right and left movers interact with each other and also with themselves. A remarquable feature here is that the string equations of motion in the D-dimensional AS geometry are exactly solvable.

The procedure of ref.17 to derive a shock wave metric starting from a solution of the Einstein equations can be easily extended to D dimensions. Let be a solution of the Einstein equations given by

$$dS^2 = 2\,A\,(u,\,v')\,du\,dv' + g\,(u,v')\,(dx^i)^2 \qquad (134)$$

$$u = t-X \qquad 1 \leq i \leq D-2$$
$$v = t+X$$

Let us make the shift

$$v \to v' + f(X^i) \qquad \text{for } u > 0$$

Then, the metric eq. (134) reads

$$ds^2 = 2\,A\,(u,v)\,du\,dv + g\,(u,v)\,(dx^i)^2$$
$$= 2\,A\,(u,v)\,f\,(X^i)\,\delta(u)\,du^2 \qquad (135)$$

where $v = v' + f(X^i)\, H(u)$

$H(u)$ being the step function

Eq. (135) fulfils the Einstein equations provided

$$\partial_v A(u,v) = \partial_v g(u,v)$$

$$\frac{A}{g} \nabla_i^2 f - \frac{\partial^2_{uv} g}{g} f = 32\pi G\mu A^2 \delta^{D-2}(\rho) \tag{136}$$

where the right and side corresponds to a point source moving at the speed of light ($T_{uu} = \mu\, \delta^{D-2}(\rho)\, \delta(u)$)

If the starting metric is flat space time :
$A = 1/2$, $g = 1$

and we have

$$\nabla_i^2 f = 16\pi G\mu\, \delta^{D-2}(\rho), \qquad \rho^2 = \sum_{i=1}^{D-2} X^{i\,2} \tag{137}$$

whose solution is given by

$$f = \begin{cases} K/\rho^{D-4} & , \quad K = 16\pi G\mu/(D-4)\Omega_{D-2}, \; D>4 \\ 8G\mu \ln\rho & \quad D = 4 \end{cases}$$

Recall that the scalar Green function in D dimensions satisfies

$$\nabla^2 G = -\Omega_{D-2} \qquad , \qquad \Omega_D = \frac{2\pi^{D/2}}{\Gamma(D/2)}$$

$$G = \frac{1}{(D-4)\,\rho^{D-4}} \tag{138}$$

<u>String quantization in the Aichelburg-Sexl Geometry</u>

The Aichelburg-Sexl metric in D dimensions is given by

$$ds^2 = dU\,dV - (dX^i)^2 + f_D(\rho)\, \delta(U)\, dU^2 \tag{139}$$

where U,V are null (longitudinal) coordinates

$$U = T - X \qquad , \tag{140}$$

$$V = T + X$$

X^i are the transverse coordinates,

$$\rho = \sqrt{(X^i)^2} \qquad , \qquad 2 \le i \le D-2$$

and

$$f_D(\rho) = \begin{cases} K/\rho^{D-4} & K = \frac{8\pi^{2-D/2}}{(D-4)} G\mu\, \Gamma(\frac{D}{2}-1) \quad D>4 \\ 8G\mu \ln\rho & D = 4 \end{cases} \tag{141}$$

Here we are interested in D>4 dimensions. This metric describes the gravitational field of a ultra relativistic particle moving in the V-direction with momentum p . This represents a gravitational impulsive (or "shock") wave located at U = 0 superimposed to Minkowski space time. The only non-vanishing components of the Christoffel connections are :

$$\Gamma^V_{UU} = \partial_U G_{UU} = f_D(\rho)\ \delta'(U)$$

$$\Gamma^V_{Ui} = \partial_i G_{UU} = \partial_i f_D(\rho)\ \delta(U) = -\frac{K(D-4)}{\rho^{D-2}} X^i \delta(U) \qquad (142)$$

$$\Gamma^i_{UU} = \frac{1}{2}\Gamma^V_{Ui}$$

The equations of motion of the string

$$\Box^2 X^A + \Gamma^A_{BC}\ \partial_\mu X^B\ \partial^\mu X^C = 0 \quad ,$$

read in this metric

$$(\partial_\sigma^2 - \partial_\tau^2)\, U = 0$$

$$(\partial_\sigma^2 - \partial_\tau^2)\, V + \delta'(U)\, f_D(\rho)\left[(\partial_\sigma U)^2 - (\partial_\tau U)^2\right] + $$
$$+ 2\,\delta(U)\,\partial_i f_D(\rho)\left[\partial_\sigma U\,\partial_\sigma X^i - \partial_\tau U\,\partial_\tau X^i\right] = 0$$

$$(\partial_\sigma^2 - \partial_\tau^2)\, X^i - \frac{1}{2}\,\delta(U)\,\partial_i f_D(\rho)\left[(\partial_\sigma U)^2 - (\partial_\tau U)^2\right] = 0 \qquad (143)$$

where we have taken the world sheet metric $ds^2 = \Lambda(\sigma,\tau)(d\sigma^2 - d\tau^2)$ in the conformal gauge. Without loss of generality we can fix the gauge by setting $U = \alpha' p_U \tau$. Therefore we have

$$U = \alpha' p_U \tau$$

$$(\partial_\sigma^2 - \partial_\tau^2)\, V - \delta'(\tau)\, f_D(\rho(\sigma,\tau)) - 2\,\delta(\tau)\,\partial_\tau f_D(\rho(\sigma,\tau)) = 0$$

$$(\partial_\sigma^2 - \partial_\tau^2)\, X^i - \frac{p_U \alpha'}{2}\,\delta(\tau)\,\partial_i f_D(\rho(\sigma,\tau)) = 0 \qquad (144)$$

These equations can be recasted as

$$U = p_U \alpha' \tau$$

$$(\partial_\sigma^2 - \partial_\tau^2)\, V - \delta'(\tau)\, f_D(\rho(\sigma,\tau=0)) - \delta(\tau)\,\partial_\tau f_D(\rho(\sigma,\tau)) = 0$$

$$(\partial_\sigma^2 - \partial_\tau^2)\, X^i - \frac{p_U \alpha'}{2}\,\delta(\tau)\,\partial_i f_D(\rho(\sigma,\tau)) = 0 \qquad (145)$$

where we have used the property

$$f(\tau)\ \delta'(\tau) = f(0)\ \delta'(\tau) - \dot{f}(0)\ \delta(\tau)$$

Eqs (145) can be exactly solved. The transverse coordinates X satisfy the free string equations in flat space-time except at $\tau = o$, where their derivatives are discontinuous that is

$$(\partial_\sigma^2 - \partial_\tau^2)\ X^i_\chi = 0 \qquad \forall\ (\sigma, \tau \neq o)$$

and

$$\left[\partial_\tau (X^i_> - X^i_<)\right]_{\tau=o} + \frac{P_0 \alpha'}{2} \left[\partial_\tau f_D(\rho)\right]_{\tau=0} = 0 \qquad (146)$$

$$X^i_>(\sigma, o) = X^i_<(\sigma, o) \qquad (147)$$

The exact solution of eq. (145)- (147) is given by

$$U = P_0 x^1 \tau$$

$$V = F(\sigma - \tau) + G(\sigma + \tau) - \frac{1}{2} H(\tau) \left[f_D(\rho(\sigma+\tau)) + f_D(\rho(\sigma-\tau)) \right] - \frac{1}{2} H(\tau) \left[\partial_\tau f_D(\rho(\sigma+\tau)) + \partial_\tau f_D(\rho(\sigma-\tau)) \right] \qquad (148)$$

$$X^i_\chi = \overrightarrow{X}^i_\chi(\sigma - \tau) + \overleftarrow{X}^i_\chi(\sigma + \tau)$$

where

$$\rho(\sigma, \tau) = \sqrt{X^{i\,2}(\sigma, \tau)}$$

$$f_D(\rho(x)) = K / \rho_{(x)}^{D-4} \quad , \qquad \partial_\tau f_D(\rho(x)) = -\frac{K(D-4) X^i \dot{X}^i}{\rho^{D-2}}$$

$H(\tau)$ is the step function and

$$\overrightarrow{X}^i_\chi(x) = \frac{C^i(x)}{2} + \frac{E^i(x)}{2} \mp \frac{\tilde{K}}{4} P_0 \alpha' \int_{\sigma_i}^{x} d\sigma' \frac{C^i(\sigma')}{\left[\sqrt{C'^2(\sigma')}\right]^{D-2}}$$

$$\overleftarrow{X}^i_\chi(x) = \frac{C^i(x)}{2} - \frac{E^i(x)}{2} \pm \frac{\tilde{K}}{4} P_0 \alpha' \int_{\sigma_i}^{x} d\sigma' \frac{C^i(\sigma')}{\left[\sqrt{C'^2(\sigma')}\right]^{D-2}} \qquad (149)$$

here $C^i = X^i(\sigma, \tau = o)$, E^i, F and G are arbitrary functions of the indicated variables, the integration bounds σi will be obtained below and

$$\tilde{K} = \left(\frac{D-4}{2}\right) K = 4 \pi^{2 - D/2} G p\ \Gamma\left(\frac{D}{2} - 1\right) \qquad (150)$$

K is given by eq. (142). The symbol > (<) labels the solution in the $\tau > o$ ($\tau < o$) region. In the last term of eqs. (149), the upper sign corresponds to the (>) - solution and the lower sign to the (<) - solution.

Since the X^i obey the wave equation both for >o and < o, we can expand them in harmonic oscillators

$$\overrightarrow{X}^i_>(\sigma - \tau) = \frac{q^i_>}{2} - \frac{\alpha'}{2} P^i_>(\sigma - \tau) + \sqrt{\alpha'} \sum_{n \neq o} \frac{\tilde{\alpha}^i_{n>}}{n} e^{in(\sigma - \tau)} \qquad (151a)$$

$$\overleftarrow{X}^i_>(\sigma + \tau) = \frac{q^i_>}{2} + \frac{\alpha'}{2} P^i_>(\sigma + \tau) + \sqrt{\alpha'} \sum_{n \neq o} \frac{\alpha^i_{n>}}{n} e^{-in(\sigma + \tau)} \qquad (151b)$$

$\overrightarrow{X}^i_<(\sigma - \tau)$ = the same expression as eq. (151,a) with > → <

$\overleftarrow{X}^i_<(\sigma+\tau)$ the same expression as eq. (151,b) with $> \to <$ (152)

The continuity constraint eq. (147) yields

$$\overrightarrow{X}^i_>(\sigma) - \overrightarrow{X}^i_<(\sigma) = -\left[\overleftarrow{X}^i_>(\sigma) - \overleftarrow{X}^i_<(\sigma)\right]$$

$$\alpha_{n<}^i - \tilde{\alpha}_{-n<}^i = \alpha_{n>}^i - \tilde{\alpha}_{-n>}^i \quad , n \neq 0 \qquad (153)$$

$$q^i_< = q^i_>$$

In summary, we have found the exact solution to the string equations of motion in the D-dimensional AS Geometry. The longitudinal coordinate V expresses in terms of the transverse ones through eq (148). The transverse coordinates admit flat space expansions for $\tau > o$ and $\tau < o$ eqs (151) - (152) . The Fourier coefficients in both regions are related by the matching relations eqs. (II.19) - (II.22). They can be rewritten as

$$p_>^i - p_<^i = \frac{\tilde{K}}{2\pi\alpha'} \int_0^{2\pi} d\sigma\, D^i(\sigma)$$

$$\alpha_{n>}^i - \alpha_{n<}^i = \frac{i}{4\pi}\frac{\tilde{K}}{\sqrt{\alpha'}} \int_0^{2\pi} d\sigma\, e^{in\sigma} D^i(\sigma) \qquad (154)$$

$$\tilde{\alpha}_{n>}^i - \tilde{\alpha}_{n<}^i = \frac{i}{4\pi}\frac{\tilde{K}}{\sqrt{\alpha'}} \int_0^{2\pi} d\sigma\, e^{-in\sigma} D^i(\sigma)$$

This is the exact non-linear transformation relating the creation and annhilation operators for $\tau > o$ and $\tau < o$. Notice here that D^i is a non-linear functionnal of the operators $(\alpha_{n<}^i - \tilde{\alpha}_{-n<}^i)$

$$D^i(\sigma) = \frac{P_0 \alpha' C^i(\sigma)}{\left[\sqrt{(C)^2(\sigma)}\right]^{D-2}} \quad , \quad C^i(\sigma) = X^i(\tau = 0) = q^i + \sqrt{\alpha'} \sum_{n \neq 0} \frac{e^{-in\sigma}}{n}(\alpha_{n<}^i - \tilde{\alpha}_{-n<}^i)$$

The energy-momentum tensor

$$T_{\pm\pm}(\sigma,\tau) = G_{AB}(X)\, \partial_\pm X^A\, \partial_\pm X^B \qquad (155)$$

reads in this metric

$$T_{\pm\pm}(\sigma,\tau) = \partial_\pm U\, \partial_\pm V - (\partial_\pm X^i)^2 + \delta(U)\, f_D(\rho)(\partial_\pm U)^2$$

where

$$x_\pm = (\sigma \pm \tau) \quad , \quad \partial_\pm = \frac{1}{2}(\partial_\sigma \pm \partial_\tau)$$

From eqs (148) we find

$$\left(T_{\pm\pm}\right)_< = \left(T_{\pm\pm}\right)_{<\,\text{flat}} \qquad \tau < 0 \qquad (156)$$

$$\left(T_{\pm\pm}\right)_> = \left(T_{\pm\pm}\right)_{>\,\text{flat}} + \frac{P_0 \alpha'}{2} H(\tau)\, \partial_\pm \left[f_D(\sigma \pm \tau) - \dot{f}_D(\sigma \pm \tau)\right] \qquad \tau > 0$$

where

$$\left(T_{\pm\pm}\right)_{\gtrless\,\text{flat}} = \pm P_0 \alpha'\, \partial_\pm V_{\text{flat}} - \left(\partial_\pm X^i_{\gtrless}\right)^2 \qquad (157)$$

$f_D(\sigma,\tau)$ and $\dot{f}_D(\sigma\pm\tau)$ are given by eqs. (148) and V_{flat} is just the free part of the solution for the V-coordinate (eq. 148)

$$V_{flat}\ F(\sigma-\tau) + G(\sigma+\tau)$$

In the light-cone gauge where we are working, these constraints completely determine the V coordinate of the string

$$\pm\,\partial_\pm V_{flat} = \frac{1}{\rho_0\alpha'}\left(\partial_\pm X^i_<\right)^2 , \quad \tau<0 \tag{158}$$

$$\pm\,\partial_\pm V_{flat} = \frac{1}{\rho_0\alpha'}\left(\partial_\pm X^i_>\right)^2 - \frac{1}{2}\,\partial_\pm\left[f_D(\sigma\pm\tau) - \dot{f}_D(\sigma\pm\tau)\right], \quad \tau>0 \tag{159}$$

This formula gives the solution of the constraints. It can be checked from the transverse solution of the equations of motion that eq. (159) is a consequence of eq. (158) as it should be.

The conformal generators

$$L_n = \int_0^{2\pi} d\sigma\, e^{in\sigma}\, T_{\pm\pm}(\sigma, \tau=0)$$

can be computed in terms of the $\tau<0$ basis or in terms of the $\tau>0$ basis. As T_{++} is conserved, the L_n generators computed in the < and > - basis are the same. We have

$$\begin{aligned} L_n &= L_{n\,flat}(\alpha_<, \tilde{\alpha}_<) = \\ &= L_{n\,flat}(\alpha_>, \tilde{\alpha}_>) + \Delta L_n(\alpha_>) \end{aligned} \tag{160}$$

where L_n flat is the standard free expression

$$L_{n\,flat}(\alpha,\tilde{\alpha}) = \sum_m \left(\alpha^i_m\,\alpha^i_{n-m} + \tilde{\alpha}^i_m\,\tilde{\alpha}^i_{n-m}\right) \tag{161}$$

and ΔL_n stand for the Fourier components of eq. (156)

In particular,

$$\begin{aligned} L_0 &= L_{0<\,flat} \\ &= L_{0>\,flat} + \frac{\rho_0\alpha'}{2}\left[f_D(2\pi) - f_D(0)\right] \mp \frac{\rho_0\alpha'}{2}\left[\dot{f}(2\pi) - \dot{f}(0)\right] \end{aligned} \tag{162}$$

Here the argument of f_D indicates the value of σ (τ = o is omitted) and

$$L_{0\,flat} = \frac{1}{2}\sum_m \left(\alpha^i_{-m}\,\alpha^i_m + \tilde{\alpha}^i_m\,\tilde{\alpha}^i_{-m}\right) + 2P_+P_- \tag{163}$$

The mass formula follows from the $L_0 \approx 0$ constraint

$$\begin{aligned} M^2 - M^2_{flat} &= \frac{1}{\alpha'}\sum_{n=1}^{\infty}\left(\alpha^{i+}_{n<}\alpha^i_{n<} + \tilde{\alpha}^{i+}_{n<}\tilde{\alpha}^i_{n<}\right) = \\ &= \frac{1}{\alpha'}\sum_{n=1}^{\infty} n\left(a^{i+}_n a^i_n + \tilde{a}^{i+}_n \tilde{a}^i_n\right) \end{aligned} \tag{164}$$

where

$$\alpha^i_n = -i\sqrt{|n|}\,(\mathrm{sgn}\, n)\, a^i_n .$$

The mass spectrum is the same as in flat space time but there is an scattering effect on the string due to the shock wave geometry. The term ΔL_n describes the excitations between the internal (particle) states of the string due to this scattering. The expression of L_0 in terms of $\alpha_>$ is different from the flat space expression but the spectrum is the same. The critical dimension at which massless states appear is D=26, the same as in flat space .

Scattering amplitudes and pair creation

The transformation eq. (154) mixes non-linearly the particle and antiparticle modes and the right and left movers. This transformation contains exactly all the information concerning the interaction of the string with the AS geometry, the elastic and inelastic scattering and pair creation process. In order to get more explicit expressions for these processes we will express the exact solution as

$$X^i(\sigma,\tau) = q^i(\tau) + \eta^i(\sigma,\tau) , \qquad (165)$$

that is, an in refs (2,3) we expand X^i around the center of mass solution plus fluctuations around it.Here eq.(165) is the exact solution of the equations of motion. At the first order in η^i we have

$$D^i(\sigma) = \frac{P_0 \alpha'}{(q_\ell^2)^{\frac{D}{2}-1}} \left[q^i + \Delta_{ij} \eta^j + O(\eta^2) \right] \qquad (166)$$

where

$$\Delta_{ij} = \delta_{ij} - (D-2) \frac{q_i q_j}{(q_\ell^2)} \qquad (167)$$

All quantities here are taken at $\tau = o$. (Δ_{ij} identically satisfies

$$\mathrm{Tr}\,\Delta_{ij} = 0$$

From eqs. (154) and (167) we get the linearized transformation

$$P_>^i - P_<^i = \frac{\tilde{K} P_0}{(q_\ell^2)^{\frac{D}{2}-1}} q^i + O(\eta^2) \qquad (168)$$

Notice that

$$\alpha_{-n} = \alpha_n^+ \quad , \quad \tilde{\alpha}_{-n} = \tilde{\alpha}_n^+$$

For the oscillators we get the linearized transformation

$$\begin{aligned} \alpha_{n>}^i &= (\delta_j^i + B_n{}^i{}_j)\, \alpha_{n<}^j - B_n{}^i{}_j\, \tilde{\alpha}_{n<}^{j+} \\ \tilde{\alpha}_{n>}^i &= (\delta_j^i + B_n{}^i{}_j)\, \tilde{\alpha}_{n<}^j - B_n{}^i{}_j\, \alpha_{n<}^{j+} \end{aligned} \qquad (169)$$

with

$$B_n{}^i{}_j = \frac{i}{2n} \frac{\tilde{K} P_0 \alpha'}{(q_\ell^2)^{\frac{D}{2}-1}} \Delta^i_j = i \frac{\Delta^i_j}{n} \frac{2\pi^{2-D/2}}{(q_\ell^2)^{\frac{D}{2}-1}} P_0 \alpha' G_\beta \Gamma(\tfrac{D}{2}-1) \qquad (170)$$

This is a Bogoliubov transformation expressing the particle operators at $\tau > 0$ as a linear combination of the particle and antiparticle operators at $\tau < 0$.

For fixed n, transitions take place between the internal oscillatory modes of the string. Notice that the effect of mixing particle and antiparticle modes changes at the same time their right or left character. There is also an effect on the polarization of the modes (without changing their right or left character). The number of left modes minus the number of right modes stays equal to zero in both processes. In other words, if for $\tau < o$, the string has a right (or left) excited mode with a given polarization j, then for $\tau > o$ there will be : (i) an amplitude ($\delta_{ij} + \beta_n^i{}_j$) for a right (or left) mode polarized in the i-direction and (ii) an amplitude $\beta_n^i{}_j$ for a left (or right) anti-particle mode polarized in the i-direction ($2 \leq i \leq D-2$)

Let us define the ingoing vacuum state $|0_< >$ at $\tau < o$:

$$\alpha_{n<}^i |0_< > = 0 \text{ for all } n \tag{171}$$

Then we find

$$\langle 0_< | N_{n>}^i | 0_< \rangle = \langle 0_< | \alpha_{n>}^{i+} \alpha_{n>}^i | 0_< \rangle = \frac{1}{2} | \beta_{jn}^i |^2 \tag{172}$$

$$\langle 0_< | \tilde{N}_{n>}^i | 0_< \rangle = \langle 0_< | \tilde{\alpha}_{n>}^{i+} \tilde{\alpha}_{n>}^i | 0_< \rangle = \frac{3}{2} | \beta_{jn}^i |^2$$

that is,

$$N_n^i = \langle 0_< | N_{n>}^i + \tilde{N}_{n>}^i | 0_< \rangle = | \beta_{jn}^i |^2$$

where $$| \beta_{jn}^i |^2 = \frac{1}{4n^2} \frac{\tilde{K}^2 (\rho_0 \alpha')^2}{(q_\ell^2)^{D-2}} (D^2 - 5D + 8) \tag{173}$$

$\tilde{K}$ is given by eq.

This represents the number of modes for $\tau > o$ at the nth-level created from the $\tau < o$ vacuum. That is, pair creation out of the $\tau < 0$ vacuum state takes place for $\tau > o$ and in <u>all</u> the modes as a consequence of the scattering by the shock wave geometry. Each pair here is formed by a right and left mode. The total number over all n is

$$\mathcal{N} = \sum_n N(n) = \left[\rho_0 \alpha' \frac{(D-4)}{4} \frac{\tilde{K}}{\rho_0^{D-2}} \right]^2 (D^2 - 5D + 8) \frac{\pi^2}{6} \tag{174}$$

where $$\rho_0 = \sqrt{q^{\mu 2}(0)}$$

We see that the excitation of the string by the geometry is inversely proportional to the center of mass impact parameter ρ_0, for large ρ_0.

We can also write

$$\alpha_{n>}^{i} = e^{G}\, \alpha_{n>}^{i}\, e^{-G}$$

where $G = \sum_n \theta_n \left(\alpha_{n<}^{+} \tilde{\alpha}_{n<}^{+} - \alpha_{n<} \tilde{\alpha}_{n<} \right)$

and

$$\operatorname{th} \theta_n = \frac{\beta_n}{(1+\beta_n)}$$

Therefore,

$$|0_>\rangle = e^{G}\, |0_<\rangle$$

where

$$\alpha_{n>}^{i}\, |0_>\rangle = 0 \qquad \forall n$$

<u>The center of mass motion and string cross section</u>

We use lower case letters for the center of mass (c.m.) motion and keep capital ones for the string solutions. The center of mass trajectory is just the motion of a test particle in curved space time, that is

$$\ddot{q}^{A}(\tau) + \Gamma^{A}_{BC}(q)\, \dot{q}^{B}\, \dot{q}^{C} = 0 \tag{174}$$

The (c.m) solution always admits the constant of motion

$$\alpha'^{2} m^{2} = - G_{AB}(q)\, \dot{q}^{A}\, \dot{q}^{B} \quad , \tag{175}$$

which defines the (classical) mass of the string in the curved geometry. The goedesic equations (174) read

$$\begin{aligned}
&\frac{d^2 u}{d\tau^2} = 0 \\
&\frac{d^2 v}{d\tau^2} + f_D(\rho)\, \delta'(u) \left(\frac{du}{d\tau}\right)^2 + 2\, \partial_\tau f_D(\rho)\, \delta(u) \left(\frac{du}{d\tau}\right) = 0 \\
&\frac{d^2 q^i}{d\tau^2} + \frac{1}{2}\, \partial_i f_D(\rho)\, \delta(u) \left(\frac{du}{d\tau}\right)^2 = 0
\end{aligned} \tag{176}$$

which can be written as

$$\begin{aligned}
&u = p_u \alpha' \tau \\
&\frac{d^2 v}{d\tau^2} + f_D(\rho_0)\, \delta'(\tau) + \dot{f}_D(\rho_0)\, \delta(\tau) = 0 \\
&\frac{d^2 q^i}{d\tau^2} + \frac{1}{2}\, \partial_i f_D(\rho_0)\, p_u \alpha'\, \delta(\tau) = 0 \quad , \quad \rho_0 = \sqrt{q^{i\,2}(0)}
\end{aligned} \tag{177}$$

The general solution is given by

$$\begin{aligned}
u &= p_u \alpha' \tau \\
v &= p_v \alpha' \tau - \dot{f}_D(\rho_0)\, \tau\, H(\tau) - f_D(\rho_0)\, H(\tau)
\end{aligned}$$

$$q^i = q_0^i + p_0^i \alpha' \tau - \frac{1}{2} \partial_i f_D(\rho_0)\, p_u \alpha' \tau\, H(\tau) \tag{178}$$

here

$$\begin{aligned} q_0^i &\equiv q^i(0) \\ p_0^i &= \frac{1}{\alpha'} \left[\dot{q}^i(\tau) \right]_{\tau=0^-} \equiv p_{0<}^i \end{aligned} \tag{179}$$

The c.m. trajectory follows continuous straight lines at $\tau = 0$ in the transverse ($1 \leq i \leq D-2$) directions with discontinuous momenta

$$\begin{aligned} p_{0>}^i - p_{0<}^i &= -\frac{p_u}{2} \partial_i f_D(\rho_0) \\ (q_{0>}^i &= q_{0<}^i) \end{aligned} \tag{180}$$

The motion is discontinuous at $\tau = 0$ in the v-direction.

Notice that

$$\dot{q}^i(0) = \alpha' p_0^i - \frac{\alpha' p_u}{4} \partial_i f_D(\rho_0)$$

and

$$\dot{f}_D(\rho_0) = \dot{q}^i(0)\, \partial_i f_D(\rho_0) = \alpha' p_0^i \partial_i f_D(\rho_0) - \frac{\alpha' p_u}{4} \left[\partial_i f_D \right]^2 \tag{181}$$

The mass of the c.m. solution can be easily computed from eq.(175), that is

$$\alpha'^2 m^2 = \left(\frac{dq^i}{d\tau} \right)^2 - \left(\frac{dv}{d\tau} \right) p_u \alpha' - f_D(\rho_0)\, \delta(\tau)\, p_u \alpha' \tag{182}$$

By replacing the solution given by eqs. (178) and by using eq. (181), the $H(\tau)$ and $\delta(\tau)$ dependences cancel out as it should be and we have

$$m^2 = p_0^{i\,2} - p_u p_v \tag{183}$$

Now, we can write the trajectories as

$$\begin{aligned} v &= \frac{(p_0^{i\,2} - m^2)}{p_u^2} u + \left\{ \frac{1}{4} \left[\partial_i f_D(\rho_0) \right]^2 - \frac{p_0^i}{p_u} \partial_i f_D(\rho_0) \right\} u\, H(u) - \\ &\quad - f_D(\rho_0)\, H(u) \\ q^i &= q_0^i + \frac{p_0^i}{p_u} u - \frac{1}{2} \partial_i f_D(\rho_0)\, u\, H(u). \end{aligned} \tag{184}$$

We see that the particular solutions given in eq.(9) of ref (18) correspond to take $m = 0$ and $p_0^i = 0$.

Let us consider now the scattering angle of the particle as a function of its impact parameter. ρ_0 is the distance from the origin to the point where the particle trajectory intersects the $u = o$ ($x = t$) plane (eq. 178). If we call φ the angle between $\vec{\rho}_0$ and the ingoing velocity we have

$$\sin \varphi = \frac{p_{x<}}{|\vec{p}_<|} = \frac{p_{x<}}{\sqrt{p_x^2 + p_0^{i\,2}}} \tag{185}$$

where

$$p_x = \frac{1}{2} (p_v - p_u)$$

Therefore

$$b = \rho_0 \sin\varphi$$

Now the scattering angle Θ is just the angle between the ingoing and outgoing momenta, that is

$$\cos\Theta = \frac{\vec{p}_> \cdot \vec{p}_<}{|\vec{p}_>||\vec{p}_<|} = \frac{1 + \dfrac{\alpha' p_0^i \left(p_0^i - \frac{p_\nu}{2}\partial_i f_D\right)}{p_x \left(p_x \alpha' - f_D/2\right)}}{\sqrt{1 + \dfrac{p_0^{i\,2}}{p_x^2}}\ \sqrt{1 + \dfrac{\alpha'^2 \left(p_0^i - \frac{p_\nu}{2}\partial_i f_D\right)^2}{\left(p_x \alpha' - \frac{1}{2} f_D\right)^2}}} \tag{186}$$

For $\rho_0 \to \infty$ $(\Theta \ll 1)$ we get

$$\Theta_{\rho_0 \to \infty} = \frac{\tilde{K}}{\rho_0^{D-3}\,\vec{p}^{\,2}} \sqrt{(p_\nu p_x)^2 + (p_0^{i\,2} - 2 p_\nu p_x)\left(\frac{q_0^j p_0^j}{\rho_0^2}\right)^2}$$

$$= \frac{4G\mu}{\rho_0^{D-3}}\ \pi^{2-D/2}\ \Gamma\left(\frac{D}{2} - 1\right) R(\varphi) \tag{187}$$

$$R(\varphi) = \frac{1}{\vec{p}^{\,2}} \sqrt{(p_\nu p_x)^2 + (p_0^{i\,2} - 2 p_\nu p_x)\, p_0^{i\,2} \cos^2\varphi}$$

The D dimensional c.m. cross section is given by

$$\frac{d\sigma_D}{d\Omega_{D-1}} = \left(\frac{b(\Theta, \Phi)}{\sin\Theta}\right)^{D-3} \frac{1}{\left|\dfrac{d\Theta}{db}\right|_{\Phi}}, \qquad d\sigma_D = b^{D-3}\, db\, d\Omega_{D-2} \tag{188}$$

where the azymutal variable Φ is the angle between the planes $(p_>^i, p_<^i)$ $(q_0^i, p_<^i)$:

$$\cos\Phi = \operatorname{cotg}\varphi \operatorname{ctg}\Theta - \frac{q_0^i p_>^i}{\sin\varphi \sin\Theta\, |q_0|\, |p_>|} \tag{189}$$

For large b, from eqs.(187) and (188) we find

$$\left(\frac{d\sigma}{d\Omega}\right)_{\substack{cm \\ \Theta \ll 1}} = \left[\frac{4G\mu\ \Gamma\left(\frac{D}{2} - 1\right)}{(D-3)}\right]^{\left(\frac{D-2}{D-3}\right)} \Theta^{-\left(D-1+\frac{1}{D-3}\right)} \left[\pi^{2-D/2} R(\varphi)\right]^{\left(\frac{D-2}{D-3}\right)} \tag{190}$$

Let us now consider the string in an initial state described by the nth-mode. The string elasti c cross section is given by

$$\frac{d\sigma}{d\Omega} = \left(\frac{d\sigma}{d\Omega}\right)_{cm} \left| \langle \overleftarrow{n}_> | \overleftarrow{n}_< \rangle \right|^2$$

$$= \left(\frac{d\sigma}{d\Omega}\right)_{cm} \left[1 - \sum_{n' \neq n} |B_{n'}|^2\right] \tag{191}$$

From eqs. (174) and (191) we get

$$\left(\frac{d\sigma}{d\Omega}\right) = \left(\frac{d\sigma}{d\Omega}\right)_{cm} \left[1 - \left(\frac{P_0 \alpha' G \hbar}{\rho_0}\right)^2 \left(\frac{1}{\rho_0}\right)^{2(D-3)} C_D \left(1 - \frac{6}{\pi^2 n^2}\right)\right] \tag{192}$$

where $C_D = (2/3)\pi^{6-D}\ \Gamma^2(D/2-1)\ (D^2-5D+8)$

and $(d\sigma/d\Omega)_{cm}$ is given by eq.(190)

<u>Compar ison with the black hole case</u>

It is interesting to compare these results with the corresponding ones for a string in the Schwarzschild geometry. In the Schwarzschild's geometry we have found

$$\begin{aligned} \tilde{\alpha}_n^i{}_{out} &= (1 - A_n)\ \tilde{\alpha}_n^i{}_{in} + B_n\ \alpha_n^{i\,+}{}_{in} \\ \alpha_n^i{}_{out} &= (1 - A_n)\ \alpha_n^i{}_{in} + B_n\ \tilde{\alpha}_n^{i\,+}{}_{in} \end{aligned} \tag{193}$$

where

$$A_n = \left(\frac{R_s}{b}\right)^{D-3} \left(\frac{i p \alpha'}{b}\right) \sqrt{\pi}\ \frac{\Gamma\left(\frac{D}{2}+1\right)}{\Gamma\left(\frac{D+1}{2}\right)} \tag{194}$$

$$B_n = \left(\frac{R_s}{b}\right)^{D-3} \left(\frac{i p \alpha'}{b}\right) \frac{\pi}{2} \left|\frac{2nb}{\alpha' p}\right|^{D/2} e^{-\left|\frac{2nb}{\alpha' p}\right|} B_D \left[1 + O\left(\frac{\alpha' p}{n}\right)\right]$$

These results hold at first order in α' and at first order in $(R_s/b)^{D-3}$. Here b, p and m are the impact parameter, momentum and mass of the center of mass respectively and

$$R_s^{D-3} = \frac{8GM}{(D-2)}\ \pi^{-\frac{(D-3)}{2}}\ \Gamma\left(\frac{D-1}{2}\right)$$

$$B_D = \left[D + 3 - i\left(\frac{D-1}{2}\right)^2\right] \frac{1}{(D-5)}\ \frac{1}{2^{(D+1)/2}}\ \frac{1}{\Gamma\left(\frac{D+1}{2}\right)}$$

Thus, we have

$$A_n = \frac{1}{b^{D-2}}\ 4i\alpha' p\, GM\, \pi^{D/2} \frac{D}{(D-1)}\ \Gamma\left(\frac{D}{2}-1\right)\left[1 + \frac{(D-1)}{D} m^2/p^2\right]$$

$$B_n = \frac{1}{b^{D-2}}\ 4i\alpha' p\, GM\, \pi^{D/2} \frac{\sqrt{\pi}}{(D-2)}\ \Gamma\left(\frac{D-1}{2}\right) B_D \left|\frac{2nb}{\alpha' p}\right|^{D/2} e^{-\left|\frac{2nb}{\alpha' p}\right|} \tag{194}$$

whereas in the AS metric we have

$$B_{n\,i}^{\,i}{}_{AS} = \frac{1}{\rho_0^{D-2}}\ 2i\alpha' p\, G\hbar\ \pi^{1-D/2}\ \Gamma\left(\frac{D}{2}-1\right) \frac{\Delta_{ij}}{n} \tag{195}$$

Notice that for the black hole geometry, $\mathcal{A}_n$ is independent of n and vanishes exponentially at high n, In the AS geometry, $\mathcal{A}_{n\,j}^{i}$ and $\mathcal{B}_{n\,j}^{i}$ differ only in δ_j^i and are proportionnal to 1/n for all n.

It is also interesting to compare the elastic scattering cross sections. In the black hole geometry we have found

$$\left(\frac{d\sigma}{d\Omega}\right)_{BH} = \left(\frac{d\sigma}{d\Omega}\right)_{\substack{cm\\BH}} \left[1 - \left(\frac{\pi\alpha' p}{b}\right)^2 \left(\frac{R_s}{b}\right)^{2(D-3)} \sum_{n'\neq n} \left|F\left(\frac{m}{p}, \frac{n'b}{\alpha' p}\right)\right|^2\right]$$

$$= \left(\frac{d\sigma}{d\Omega}\right)_{\substack{cm\\BH}} \left[1 - \left(\frac{\alpha' p GM}{b}\right)^2 \left(\frac{1}{b}\right)^{2(D-3)} a_D \sum_{n'\neq n} \left|F\left(m/p, \frac{n'b}{\alpha' p}\right)\right|^2\right] \quad (196)$$

Where $\sum|F|^2$ is dimension less and a_D a factor only depending on D

$$a_D = \left[\frac{8}{D-2}\ \Gamma\left(\frac{D-1}{2}\right)\right]^2 \pi^{D-3} \quad .$$

In the AS geometry we have

$$\left(\frac{d\sigma}{d\Omega}\right)_{AS} = \left(\frac{d\sigma}{d\Omega}\right)_{\substack{cm\\AS}} \left[1 - \left(\frac{\alpha' p\, G\mu}{\rho_0}\right)^2 \left(\frac{1}{\rho_0}\right)^{2(D-3)} C_D \left(1 - \frac{G}{\pi^2 n^2}\right)\right]$$

where $C_D = (2/3)\pi^{6-D}\ \Gamma(D/2-1)\ (D^2-5D+8)$ (197)

We see that the classical result $(d\sigma/d\Omega)_{cm}$ gets corrections of order α'^2 in the black hole case and in the AS geometry. The dependence on b and on the metric parameters of the corrections are the same in the both geometries, the dependence on n is different. The deflection angles at first order in $(1/b)^{D-3}$ are respectively given by

$$\Theta_{BH} = \frac{4GM}{b^{D-3}}\ \pi^{2-D/2}\ \Gamma\left(\frac{D}{2}-1\right)\left[1-\left(\frac{D-3}{D-2}\right)\frac{m^2}{p^2}\right] \quad (198)$$

and

$$\Theta_{AS} = \frac{4G\mu}{\rho_0^{D-3}}\ \pi^{2-D/2}\ \Gamma\left(\frac{D}{2}-1\right)\frac{1}{\vec{p}^2}\sqrt{(p_0 p_1)^2 + (p_0'^2 - 2p_0 p_1)\,p_0'^2 \cos^2\varphi} \quad (199)$$

The small angle c.m. cross sections are

$$\left(\frac{d\sigma}{d\Omega}\right)_{\substack{cm\\BH}} = \left[\frac{4GM\ \Gamma\left(\frac{D}{2}-1\right)}{(D-3)}\right]^{\frac{D-2}{D-3}} \Theta^{-\left(D-1+\frac{1}{D-3}\right)} \left\{\pi^{2-D/2}\left[1+\left(\frac{D-3}{D-2}\right)\frac{m^2}{p^2}\right]\right\}^{(D-2)/(D-3)}$$

$$\left(\frac{d\sigma}{d\Omega}\right)_{\substack{cm\\AS}} = \frac{\left[4G\mu\ \Gamma\left(\frac{D}{2}-1\right)\right]^{\frac{D-2}{D-3}}}{(D-3)}\ \Theta^{-\left(D-1+\frac{1}{D-3}\right)} \left\{\pi^{2-D/2} \cdot R(\varphi)\right\}^{\frac{D-2}{D-3}}$$

For D = 4 :

$$\Theta_{BH} = \frac{4GM}{b}\left(1 + \frac{m^2}{2p^2}\right)$$

$$\Theta_{AS} = \frac{4G\mu}{\rho_0}\frac{1}{\vec{p}^{\,2}}\sqrt{(p_0 p_x)^2 + (p_0'^2 - 2p_0 p_x)p_0'^2\cos^2\varphi} \qquad (200)$$

and

$$\left(\frac{d\sigma}{d\Omega}\right)_{\substack{cm\\BH}} = \frac{(4GM)^2}{\Theta^4}\left(1 + \frac{m^2}{2p^2}\right)^2$$

$$\left(\frac{d\sigma}{d\Omega}\right)_{\substack{cm\\AS}} = \frac{(4G\mu)^2}{\Theta^4}\frac{1}{p^4}\left[(p_0 p_x)^2 + (p_0'^2 - 2p_0 p_x)p_0'^2\cos^2\varphi\right] \qquad (201)$$

When the initial momentum is collinear with the shock wave propagation (x) we have

$$\varphi = \pi/2 \quad , \quad p_0' = 0 \quad , \quad b = \rho_0 \quad .$$

and eq.(199) yields

$$\Theta_{AS} = \frac{8G\mu}{b^{D-3}}\,\pi^{2-D/2}\,\Gamma\left(\frac{D}{2} - 1\right) \qquad (202)$$

for a massless particle ($p_x = - p_0$) .
Comparing Θ_{BH} eqs.(198,200) with Θ_{AS} eq.(202) we see that the scattering angle for two massless particles is <u>twice</u> the scattering angle for a masssive and a massless particle in the large b and small Θ limit .

<u>Further perspectives and discussion</u>

It is interesting to study the scattering of the scalar particle corresponding to the string ground state in the AS geometry. The scalar vertex operator in curved space time fulfils the Klein-Gordon equation

$$(\Box^2 - \mu^2)\,T(X) = 0, \qquad \Box^2 = \frac{1}{G}\partial_A\left(\sqrt{G}\,G^{AB}\partial_B\right) \qquad (203)$$

The generalization of the flat space scattering amplitude to curved space time is given by

$$A(k_1, k_2) = \int d^2z_1\, d^2z_2\, \langle 0_c | : \Psi^*_{out}(k_2, X(z_2)) : : \Psi_{in}(k_1, X(z_1)) : |0_c\rangle \qquad (204)$$

here (k_1, k_2) are the on-shell ingoing and outgoing momenta of the scalar particle. $\Psi_{in}(k, X)$ and $\Psi_{out}(k,X)$ are solutions of eq. (203) with the boundary conditions

$$\Psi_{in}(k,X) = e^{i\,k.X}$$
$$X^* \to -\infty \qquad (205)$$

$$\Psi_{out}(k,X) = e^{ik.X}$$
$$X^{+} \to +\infty$$

X(z) in eq. (204) is the string coordinate operator and the normal ordering :: is taken with respect to the ingoing ground state $|0_<\rangle$

$$\alpha_n^{\mu}{}_< |0_<\rangle = 0 \quad , \quad n > 0$$
$$P_< |0_<\rangle = 0 \tag{206}$$

z_1, z_2 stand for the world sheet coordinates. In flat space time the amplitude eq. (204) is trivial :

$$A(k_1, k_2) = \text{const.}\ \delta^D(k_1 - k_2)$$

In the D-dimensional AS metric, the Klein-Gordon equation can be solved in closed form [20] . (The in-solution with the boundary condition eq.(205) is given by [20] .

$$\Psi_{in}(k,X) = \begin{cases} e^{i\left[\vec{k}_\perp \cdot \vec{X}_\perp - \frac{\omega V}{4} - \frac{U}{\omega}(k_\perp^2 + m^2)\right]} & U<0 \\ e^{-i\frac{\omega V}{4}} \int dp_\perp^{D-2}\, e^{i\left[\vec{p}_\perp \cdot \vec{X}_\perp - \frac{U}{\omega}(m^2 + p_\perp^2)\right]} S(\vec{k}_\perp - \vec{p}_\perp) & U>0 \end{cases} \tag{207}$$

where

$$S(\vec{k}_\perp - \vec{p}_\perp) = \int \frac{dy_\perp^{D-2}}{(2\pi)^{D-2}}\, e^{i\vec{y}_\perp \cdot (\vec{k}_\perp - \vec{p}_\perp) - i\varphi_D(|\vec{y}_\perp|)} \tag{208}$$

and $\varphi_D(|\vec{y}_\perp|)$ is the D dimensional generalization of the 't Hooft phase-shift [15] .

$$\varphi_D(s) = 4\omega K / \rho^{4-D}$$

The integral in eq. (204) covers the both regions $\tau<0$ and $\tau>0$. For $\tau>0$ one must use the string operators $X_>^{\mu}(z)$ eqs. (151, 152). Notice that they express in terms of the $\alpha_{n<}$- oscillators through the non-linear transformation eq.(154) .

It should be pointed out that the effect of the geometry manifests in the scattering amplitude eq.(204) in two combined ways : (i) in the wave function through the non-trivial S matrix eq.(208) already present in the quantum point particle theory and (ii) in the α_n^{μ} operators related to $\alpha_{n<}^{\mu}$ through the non linear transformation eq.(154) specific of the string. If one ignores the difference between the oscillators $\alpha_{n>}$ and $\alpha_{n<}$, the amplitude (A (k_1, k_2) gives the quantum point particles S matrix eq.(208). The full computation of the string amplitude A (k_1, k_2) will be the subject of a forthcoming paper.

Recently the graviton-graviton scattering has been studied in the context of superstring theory in flat space time [21] (Regge-Gribov

techniques or multiple Reggeized graviton exchange). The eikonal expression given in refs.21 and 22 correspond to the resommation of graviton exchanges in flat space time which yields the relativistic Coulombian amplitude (23,24). For example the dominant term of large b in eq. (6.20) of ref 21 (also in eq.12 of ref.22 corresponds to the relativistic Coulombian amplitude. For D = 4 the leading term in the small angle regime of ref. (21). gives the cross section :

$$\left(\frac{d\sigma}{d\Omega}\right)_{\Theta \ll 1} = \frac{4\, G^2 E^2}{(\Theta/2)^4} \tag{209}$$

This coincides with the scattering cross section of two gravitons in the graviton-exchange approximation (25). The factor 4 in eq. (209) is characteristic of ultrarelativistic particles. Notice that eq. (209) is also the scattering cross section for two identical scalar particles through one graviton exchange in the <u>ultrarelativistic</u> <u>limit</u>. Also notice that the scattering of (unpolarized) gravitons by a scalar particle of mass M in the <u>Ultrarelativistic</u> <u>limit</u> is given by

$$\left(\frac{d\sigma}{d\Omega}\right)_{UR} \underset{\Theta \ll 1}{=} 4\, \frac{G^2 M^2}{(\Theta/2)^4} \tag{210}$$

whereas that in the non-relativistic limit it is given by

$$\left(\frac{d\sigma}{d\Omega}\right)_{NR} \underset{\Theta \ll 1}{=} \frac{G^2 M^2}{(\Theta/2)^4} \tag{211}$$

Finally, recall that for large b and small Θ, the scattering cross section of massless neutral particles by any static gravitational field of mass M is equal to eq. (211). This describes only the weak (large distance) behaviour of the metric.

The resommation of string (or field theory) amplitudes in flat space time as performed in the litterature 21, 22 reproduces the linear effects (weak or large distance behaviour) of the gravitational field. Although further classical and quantum corrections are indeed present in higher gravi-Reggeon loops, their explicit evaluation and resommation does not seem simple. For high curvature one must consider the curved space time metric associated to such an enormous energy to start. Such strong gravitational effects are appropriately described by exactly solving the field equations in the curved backgrounds (the AS metric in the present case).

In ref. [27] we study the space time geometry of ultrarelativistic charged particles and their scattering. First at all, we start from the Reissner - Nordstrom solution describing the gravitational field of a particle of mass m and charge e. We apply to it a Lorentz boost, and take the ultrarelativistic limit $\gamma \to \infty$, $m = (\gamma^{-1} p) \to 0$ and $e = (\gamma^{-1/2} p_e) \to 0$, keeping the kinetic momentum p and the electromagnetic momentum p_e fixed, (here $\gamma = (1 - v^2)^{-1/2}$). We do this in four and in D dimensions and find in this way the following metric

$$ds^2 = du\,dv + dx_\perp^{i\,2} - f_D(\rho)\,\delta(u)\,du^2 \quad , \quad \rho = \sqrt{x_\perp^{i\,2}} \tag{212}$$

where

$$f_D(\rho) = \begin{cases} \dfrac{K}{\rho^{D-4}} + \dfrac{B}{\rho^{2(D-4)+1}} \quad , & D > 4 \\[2ex] K = -8\pi^{2-D/2} G p\, \Gamma\left(\frac{D}{2}-1\right) , \quad B = \dfrac{-6\pi G p_e^2}{(D-2)(2D-7)} \displaystyle\prod_{j=0}^{D-4} \frac{2D-7-2j}{2(D-3-j)} \end{cases}$$

$$f(\rho) = -8 G p \ln \rho - \frac{3}{2}\pi \frac{G p_e^2}{\rho} \quad , \quad D = 4 \tag{213}$$

We also obtain the same result by generating from flat space time, the gravitational shock wave of a boosted point particle of mass m and charge e in the ultrarelativistic limit $v \to c$, $m = (\gamma^{-1} p) \to 0$ and $e = (\gamma^{-1/2} p_e) \to 0$. The metric eq. (212) generalizes the AS metric to the case where the ultrarelativistic particle has a non - zero electromagnetic momentum p_e, besides the kinetic momentum p. It should be also noticed that this limit is a peculiar configuration for the electromagnetic field: the field is itself zero in this limit, but " its square " (the energy - momentum tensor) which generates curvature is non - zero and proportional to $\delta(u)$. On the other hand, it should be pointed out, that the boosted Reissner - Nordstrom geometry (with γ finite), is well defined in the three cases (i) $e^2 > m^2$, (ii) $e^2 < m^2$ and (iii) $e^2 = m^2$. However the ultrarelativistic limit only can be taken from the solution with $e^2 > m^2$, that is that corresponding to a point particle of mass m and charge e at the irremovable singularity $r = 0$. This is in agreement with the interpretation and the elementary particle context in which we are using this geometry: the ratio Ge^2 / m^2 is always bigger than one ($G = 10^{19}$ Gev). (This is not the case, of course, for astrophysical objects). The solutions representing black holes with $e^2 < m^2$ do not exist in the ultrarelativistic limit. And the case $e^2 = m^2$ (extreme black hole) leads in the ultrarelativistic limit to the original AS metric without any modification ($p_e = 0$).

We also study the scattering of relativistic charged particles at the Planck scale. In a frame where only one of the particles (particle 2 say) has an energy of the order of m_{pl} and both particles have masses m_1 , $m_2 \ll m_{pl}$, particle 2 is ultrarelativistic and the space time around it is described by our geometry, eq. (212). Particle 1 is a test particle since its energy is much smaller than m_{pl}. We first consider the case in which $e_1 = 0$, thus this scattering problem reduces to solve the Klein - Gordon equation in the curved space of eq. (212). This type of equation is not a well defined mathematical problem since it is a first order equation in u with a $\delta(u)$ potential. (The wave function Φ is discontinuous at u=0 and the product $\delta(u)\Phi$ is undefined).In reference [20] two rigorous procedures have been used to give sense to it: continuous and lattice regularisations. Here we are most concerned with the continuous regularisation which leads to the same phase shift as that found in reference [15] :

$$\varphi_{D\,cont}(\rho) = \frac{\omega}{4} f_D(\rho)$$

here in our problem $f_D(\rho)$ is given by eq.(210).
In D = 4 we find

$$S_{cont}(s,t) = \frac{2^{-2iG(s-m_1^2)}}{\pi |t|^{1-iG(s-m_1^2)}} \sum_{n=0}^{\infty} \frac{1}{n!}\left[\frac{-i\alpha G(s-m_1^2)\sqrt{|t|}}{4p}\right]^n$$

$$\times \frac{\Gamma\left[1 - iG(s-m_1^2) - n/2\right]}{\Gamma\left[iG(s-m_1^2) + n/2\right]} \qquad (214)$$

where $\alpha = 3/2\pi\, p_e^2$

When $p_e = 0$, we recover the scatering matrix S_{cont} of the standard AS geometry [15] :

$$S_{cont}(s,t)_{p_e=0} = \frac{1}{\pi}\left(\frac{4}{|t|}\right)^{iG(s-m_1^2)} \frac{\Gamma\left[1-iG(s-m_1^2)\right]}{\Gamma\left[iG(s-m_1^2)\right]} \qquad (214)$$

The S - matrix for $p_e \neq 0$ is an infinite superposition of the S - matrices for $p_e = 0$ and thus becomes an infinite series in (s, t) . S_{cont} for $p_e \neq 0$ exhibits an infinite sequence of imaginary poles at the values $G\,s = i\,m/2$, ($m \in \mathbb{Z}$). (Recall that for $p_e = 0$, S_{cont} exhibits poles only in the negative imaginary axis $Gs = -i\,(n+1)$, $n = 0,1,2, \ldots$).

Thus, the effect of the electromagnetic momentum p_e increases by a factor four the number of poles (or " resonances ").In ref.[27] we also obtain $S_{lattice}$ which exhibits cuts in both s and t variables and generalizes for $p_e \neq 0$ the expression given in reference [20]. We find

$$S_{cont}(s \to m_1^2, t) = S_{lattice}(s \to m_1^2, t) = \\ = -\frac{i}{\pi t} G(s - m_1^2) \tag{215}$$

that is the one graviton exchange amplitude (as in the $p_e = 0$ case) and

$$S_{cont}(s, t \to 0) = -\frac{i}{\pi t} Gs ,$$

$$S_{lattice}(s, t \to 0) = -\frac{i}{\pi t} \frac{1}{G(s - m_1^2) \ln^2(-t/4)} \left[1 - (iG/8\mu)(s - m_1^2) \right] \tag{216}$$

In ref.[27] we also compute the behaviour of S_{cont} for $s \to \infty$ with t fixed, which has a different t - dependence from that of the $p_e = 0$ case, and for the $s \to \infty$ and $t \to \infty$ regime with s / t fixed.

The scattering in which both particles 1 and 2 are charged is also discussed. In the context discussed above, the dynamics of this process is described by the Klein - Gordon equation for the charged field (particle 1 with charge e_1) in the metric of particle 2 with electromagnetic momentum p_e. Since at the ultrarelativistic limit the electromagnetic potential A_μ is a singular configuration and the $g_{\mu\nu}$ itself contains a $\delta(u)$ term, the terms $A^\mu A_\mu$ diverge. We derive the Klein - Gordon equation for this problem using the metric and the electromagnetic field for γ large but not infinite (that is, v almost but not 1) and (m, e) small (but not zero). This is the correct equation describing the dynamics of this scattering process. Since for g large but not infinite, the metric coefficient g_{uu} does not factorizes as a function of ρ times $\delta(u)$ but it is

$$g_{uu} = \frac{1}{\sqrt{(x - vt)^2 + \rho^2(1 - v^2)}} - \frac{1}{\sqrt{(x - vt)^2 + (1 - v^2)}} ,$$

the Klein - Gordon equation is very complicated to analize (even for $p_e = 0$).

It should be noticed that the effect of the charge in the scattering of ultra - high energetic particles is highly non - trivial. The effect of charge is not just to cause a shifting $G s \to G s + e_1 e_2 / 4\pi$ in the scattering amplitude as has been suggested in reference [15]. As we show in this paper, the shock wave metric itself is modified by the effect of the charge, the contribution to $f(\rho)$ of the terms with p and p_e are different. Of course,the effect found here will not always overshadow the contributions of ordinary electromagnetic interactions proportional to $e_1 e_2$ .It is not hard to see in which limit any of these effects dominates over the other.The gravitational field of the electromagnetic field is negligible as long as the impact parameter b satisfies

$$(e^2) / b \ll m ,$$

or $$(e^4) t \ll m^2, \quad \text{in Planck units,}$$

Actually ,we are dealing here with just a special case of "corrections" due to a deviation from the pointlike mass distribution of the original particles.
Particles with finite charge (e) cannot move at the speed of light. At $\gamma=\infty$ the charge should vanish as $e(\gamma) = \gamma^{-1/2} p_e$, with finite constant p_e (the mass vanishes as $m(\gamma) = \gamma^{1} p$ with constant p). An ultrarelativistic particle of momenta p and p_e can interact with a particle of mass m and zero charge, but not with a finite charge (the interaction is infinite). For γ large but finite , the interaction does not diverge . The interaction of two ultrarelativistic particles of momenta p_{e1} and p_{e2} should be also a well defined, although a very complicated non - linear collision problem. The inclusion of spin is also an interesting non- trivial problem and it is now under investigation [28].Others generalizations are given in ref.[29].

The interaction of a neutral test string with the shock wave curved geometry discussed here is well defined at the $\gamma=\infty$ limit and it is non linear.

The non linear equations of motion of a neutral test string in the curved shock wave geometry discussed here are exactly solvable. The exact general solution of the equations of motion and constraints both at the classical and quantum level, have been found in reference [19]. This solution can be easily generalized to the present charged metric just using our $f_D(\rho)$ [eq.(21)]. There is a non linear transformation relating the $\tau < 0$ oscillator operators $a^i_{n<}$ to the $\tau > 0$ operators $a^j_{n>}$ and $a^{j+}_{n>}$. The explicit expressions for the deflection angle $\Theta(\rho_0)$, (ρ_0 is the impact parameter of the center of mass of the string), hold here at the leading behaviour since the contribution to $f_D(\rho)$ of the term depending on p_e is proportional to $\rho^{-2(D-4)-1}$.

More recently generalizations of the gravitational shock wave space times have been given [see ref.29].
This problem has raised much interest recently. For other approachs see refs[30-33].

Pág. 08(20) - 1.3 The Riemannian curvature tensor
Newton's first law states that the motion of a particle is in a straight line at constant speed if no force acts upon it. Geodesics on a Riemannian manifold are understood to be subject to Newton's first law: it is considered that the straightness of a geodesic is equivalent to the existence of a parallel velocity vector field along it. In view of equation (1.2.1), this idea leads us to the definition of parallel fields along a curve.

Pág. 29(37) - The Riemann Hypothesis – a short history
Samuel J. Patterson
Abstract. This is an historical survey of the development of the Riemann Hypothesis, why it might be true and the evidence adduced in its favour. One important point is the logical distinction between the Riemann Hypothesis and the various Extended Riemann Hypotheses. This point of view brings out clearly the line of thought which seems to be that which Riemann followed and which was later investigated in detail by Jensen and Pólya.
Keywords. Riemann zeta function, Riemann Hypothesis, Bessel functions, xi function, asymptotic analysis.
2010 Mathematics Subject Classification. 11M26, 11L07, 34M30.
1 Introduction
The short paper of 1859, reprinted in [19, pp. 177–185], in which Riemann investigated the distribution of prime numbers and their relationship to the Riemann zeta function was intended as an announcement to be followed later by a more complete paper. Riemann makes this clear in a letter to Weierstraß [19, p. 823]. The paper itself was occasioned by Riemann's election to the Berlin Academy and, apparently, a happy visit to Berlin. Riemann had spent three semesters as a student in Berlin (1847–1849). In 1852 Dirichlet visited Göttingen twice and, as Dedekind reports [19, p. 578] Riemann had long and useful conversations with him. J. T. Saccoman has informed me that Chebychev, whose work on the distribution of prime numbers had just been completed at this time, visited Dirichlet in Berlin at the end of October, 1852. Although this was presumably after the Göttingen visit one can be fairly certain that the news of Chebychev's work reached Göttingen soon afterwards – especially as Gauss' conjectures on the distribution of prime numbers seem to have been widely known. At least Riemann refers to them in his paper as if this were the case.
1 (As far as we know the first person to whom Gauss communicated his ideas was his erstwhile student

Johann Franz Encke (1791–1865) in a letter as late as 24.12.1849 – see [1, pp. 50–51]. On the other hand Legendre's rather less precise ideas were published in their first version in 1798, more than fifty years earlier. Riemann also refers to C.W. Benjamin Goldschmidt (1806–1851), an astronomer who was Gauss' assistant, but who does not seem to have added anything substantial to Gauss' contribution.)
One may therefore
place the origins of Riemann's thinking about the distribution of the primes to between the beginning of 1850, when he was working on his doctoral thesis, and the end of 1852. Although the "Riemann" zeta function was used by Euler and others, such as C. J. Malmstén and O. Schlömilch, Riemann, who had completed his systematic development of complex analysis in 1851, was the first to study this function from that point of view and to establish its basic properties as a meromorphic function. For some further interesting comments on these matters,the origin of Riemann's paper and the contributions of Malmstén and Schlömilch to the theory of the Riemann zeta function see [23, pp. 8–9].

Pág. 01(09) - 1 Calculus in curved space

In this chapter I attempt to motivate and explain the main ideas and suggest images that illustrate the mathematical apparatus of differential geometry. The actual explanations start in Sec. 1.2.2. Additional literature on differential geometry from a mathematical viewpoint is [22, 11]. A more modern mathematical textbook (which I did not read) is [17].
1.1 Summary
General Relativity (GR) is a currently well-established physical theory of gravitation whose mathematical apparatus is based on differential geometry (more specifically, tensor calculus in curved spaces). In this chapter, I introduce the main concepts of this calculus: manifolds, tangent spaces, covariant derivatives, and curvature. I will explain and use the index-free notation. You (the reader) will perhaps appreciate this material more fully if you are already somewhat familiar with tensor calculus and GR, at least to the extent covered in Appendix A.
The pragmatic side of this chapter is to develop sufficiently powerful formalism for index-free calculations, which will be heavily used throughout this book. You may skip this chapter on first reading iff 1 you are familiar with the following concepts and notations.

In this set of coordinates the distances are the Euclidean ones (with the correct variables), but what is the meaning of T? T is the time time marked by clocks synchronized with light signals.

Pág. 35 – Curvature and Gravity.

We have already seen that there is an important difference between a "fake" gravitational field and an "honest" one: in particular to have a "honest" gravitational field there cannot exist a global change of coordinates such that the metric can be read as the Minkowski one. Let's observe that in a flat space (like Minkowski space) the parallel transport does not depends by the path. In fact since the Christoffel symbols are null

$$\frac{DV^\mu}{d\lambda} = \frac{dV^\mu}{d\lambda} = 0$$

Pág. (09)

Here the initial assumption of uniform motion is avoided. This method shows also that the composition equations are also valid if the Lorentz multiplier is used

* *Einstein's composition rule*: Denoting the magnitudes of the velocity of the point P in S and S' by

$$u = \sqrt{(u_x^2 + u_y^2 + u_z^2)}, \qquad u' = \sqrt{(u'^2_x + u'^2_y + u'^2_z)} \tag{3}$$

and by θ the angle between v and u', the magnitude squared of u is found from the above equations as

$$u^2 = \frac{v^2 + u'^2 + 2vu'\cos\theta - (vu'/c.\sin\theta)^2}{\left(1 + (vu'/c^2)\cos\theta\right)^2} \tag{4}$$

or

$$u = \frac{\sqrt{\left\{v^2 + u'^2 + 2vu'\cos\theta - (vu'/c.\sin\theta)^2\right\}}}{1 + (vu'/c^2)\cos\theta} \tag{5}$$

This is Einstein's composition rule.

* *Reduction to two-dimensional form*: If it is assumed, as is always possible, that the axes for x and y are taken in the plane of the two velocities u' and v the equation for the z direction becomes redundant and the equations take the most used form

$$u_x = \frac{u'_x + v}{\{1 + v\, u'_x/c^2\}} \qquad u'_x = \frac{u_x - v}{(1 - v\, u_x/c^2)}$$

$$u_y = \frac{\sqrt{(1-v^2/c^2)}\, u'_y}{\{1 + v\, u'_x/c^2\}} \qquad u'_y = \frac{\sqrt{(1-v^2/c^2)}\, u_y}{(1 - v\, u_x/c^2)} \tag{6}$$

where the last equation has been written using the square root to emphasis the characteristic reduction of the transverse component of velocity by this factor. In the one-dimensional case suffices can be omitted giving

$$u = \frac{u' + v}{(1 + v\, u'/c^2)} \qquad u' = \frac{u - v}{(1 - v\, u/c^2)} \tag{7}$$

Pág. (10) – 4. The Lorentz Group

The Lorentz group was at first defined by Poincaré (1905) for one dimensional motion and then (1906) as the group generated by the Lorentz translations in the x, y, and z directions. These generate also the group of spatial rotations which consequently is a subgroup of the Lorentz group. The group contains only homogeneous transformations in x, y, z, t and is what would now be called the restricted homogeneous Lorentz group. It only contains transformations retaining the sense of direction of t, i.e.it is orthochronos in current terminology. As defined by Poincaré, it may include optionally scalar multiplication (dilations) but following customary practice, this scalar will (for the present) be taken unity.

##References:

1) Poincaré, Comptes Rendus Paris 1905, Rendiconti Palermo1906. What is nowadays called the "Poincaré group" occurred first in Minkowski's Space-Time lecture.
2) Sommerfeld, Lectures on Theoretical Physics, vol.3.

Pág. (11) - 5- The Pseudo-Euclidean Space

Towards the end of his 1906 paper Poincaré introduced the pseudo-Euclidean space with distance-squared function

$$x^2 + y^2 + z^2 - (ct)^2$$

Notes:

1) Minkowski used the Lorentz form of the Maxwell-Herz equations which can be written concisely using modern suffix notation with summation convention as

$$\frac{\partial f_{ij}}{\partial x_i} = \rho_j \qquad \frac{\partial f^*_{ij}}{\partial x_i} = 0 \qquad i, j = 1, 2, 3, 4$$

where the arrays f and f^* are skew symmetric matrices of the electromagnetic and magnetic vectors and the ρ_j give the four dimensional charge density vector.

2) Sommerfeld developed the Minkowski notation in his *Ann. Phys* 1909 paper, referred to in the next chapter, in his papers in *Ann. Phys* 1910 on vector analysis and vector calculus, and in his later book: *Lectures on Mathematical Physics.*

3) The view of Minkowski space as flat and essentially Euclidean of course also derives from General Relativity owing to the vanishing of the Riemann-Christoffel tensor. This however has no connexion with the non-Euclidean aspect referred to here as seen later.

CHAPTER 2 - Product of Lorentz Translations

1. The Standard Form of a Lorentz Translation.

The standard form for the Lorentz translation for a velocity **v** having components v_1, v_2, v_3 will be taken to be

$$\begin{bmatrix} cdt' \\ dx' \\ dy' \\ dz' \end{bmatrix} = \begin{bmatrix} \gamma & -\gamma v_1/c & -\gamma v_2/c & -\gamma v_3/c \\ -\gamma v_1/c & 1+(\gamma-1)n_1^2 & (\gamma-1)n_1 n_2 & (\gamma-1)n_1 n_3 \\ -\gamma v_2/c & (\gamma-1)n_2 n_1 & 1+(\gamma-1)n_2^2 & (\gamma-1)n_2 n_3 \\ -\gamma v_3/c & (\gamma-1)n_3 n_1 & (\gamma-1)n_3 n_2 & 1+(\gamma-1)n_3^2 \end{bmatrix} \begin{bmatrix} cdt \\ dx \\ dy \\ dz \end{bmatrix} \tag{1}$$

where n_1, n_2, n_3 are components of the unit vector **n** in the direction of the velocity. The matrix of coefficients is symmetric and its inverse is obtained by changing v to –v. The relation can be written more concisely using partitioned matrices as

$$\begin{bmatrix} cdt' \\ \mathbf{dr'} \end{bmatrix} = \begin{bmatrix} \gamma & -\gamma \mathbf{v}^T/c \\ -\gamma \mathbf{v}/c & I+(\gamma-1)\mathbf{nn}^T \end{bmatrix} \begin{bmatrix} cdt \\ \mathbf{dr} \end{bmatrix} \tag{2}$$

Bold letters are used for 3x1 column vectors for emphasis. Using nondimensional parameters β (= v/c) and γ the transformation is

$$\begin{bmatrix} cdt' \\ dx' \\ dy' \\ dz' \end{bmatrix} = \begin{bmatrix} \gamma & -\beta\gamma n_1 & -\beta\gamma n_2 & -\beta\gamma n_3 \\ -\beta\gamma n_1 & 1+(\gamma-1)n_1^2 & (\gamma-1)n_1 n_2 & (\gamma-1)n_1 n_3 \\ -\beta\gamma n_2 & (\gamma-1)n_2 n_1 & 1+(\gamma-1)n_2^2 & (\gamma-1)n_2 n_3 \\ -\beta\gamma n_3 & (\gamma-1)n_3 n_1 & (\gamma-1)n_3 n_2 & 1+(\gamma-1)n_3^2 \end{bmatrix} \begin{bmatrix} cdt \\ dx \\ dy \\ dz \end{bmatrix} \tag{3}$$

Equivalently, using partitioned matrices,

$$\begin{bmatrix} cdt' \\ \mathbf{dr'} \end{bmatrix} = \begin{bmatrix} \gamma & -\gamma\beta \mathbf{n}^T \\ -\gamma\beta \mathbf{n} & I+(\gamma-1)\mathbf{nn}^T \end{bmatrix} \begin{bmatrix} cdt \\ \mathbf{dr} \end{bmatrix} \tag{4}$$

The characteristic operator here is the 3x3 matrix

$$I + (\gamma\text{-}1)\,\mathbf{nn}^T = (I - \mathbf{nn}^T) + \gamma\,\mathbf{nn}^T \tag{5}$$

This can also be considered vectorially as a dyadic (Silberstein 1914). When this matrix acts on any vector, the first term on the right forms the component of the vector perpendicular to **n** while the second term stretches the vector by a factor γ in the direction **n.** Thus if $^\perp$ denotes component perpendicular to **n,**

$$\{(I - \mathbf{nn}^T) + \gamma\,\mathbf{nn}^T\}\mathbf{dr} = \mathbf{dr}^\perp + \gamma\,\mathbf{n}\,(\mathbf{n}^T\mathbf{dr}) \tag{6}$$

2. The Product of Lorentz Translations.

The explicit representation of the product of two Lorentz translations has been an enduring problem of Special Relativity. Since a Lorentz translation has a symmetric matrix it is clear that such a product will not also be a Lorentz translation. As is now well known, it is a Lorentz translation either followed or preceded by a spatial rotation. This important observation was apparently first made by Silberstein (1914) So that the composition of L_1 followed by L_2 may be written

$$L_2 L_1 = R L_r = L_l R \tag{1}$$

R is a spatial rotation matrix and L_r and L_l the corresponding right and left Lorentz translations resulting from the composition. Here it is has been assumed that the rotation matrices for right and left multiplication are the same and this fact will be clear from the canonical form shown below.

Note first that relations (1) imply on taking transposes that

$$L_1 L_2 = L_r R^{-1} = R^{-1} L_l \tag{2}$$

since the Lorentz translation matrices are symmetric and the transpose of a rotation matrix gives its inverse.

* *The canonical form*: The relation between right and left Lorentz translations can be more clearly demonstrated as follows. Using the right hand Lorentz translation, let us write the product as

$$\begin{bmatrix} 1 & 0 \\ 0 & \Omega \end{bmatrix} \begin{bmatrix} \gamma & -\beta\gamma\mathbf{n}^T \\ -\beta\gamma\mathbf{n} & I+(\gamma-1)\mathbf{n}\mathbf{n}^T \end{bmatrix} \tag{3}$$

Here Ω is a 3x3 rotation matrix.

This product is

$$\begin{bmatrix} \gamma & -\beta\gamma\mathbf{n}^T \\ -\beta\gamma\Omega\mathbf{n} & \Omega+(\gamma-1)(\Omega\mathbf{n})\mathbf{n}^T \end{bmatrix} \tag{4}$$

It is now convenient to introduce the unit vector $\mathbf{n}'$

$$\mathbf{n}' = \Omega\,\mathbf{n} \tag{5}$$

so that Ω turns $\mathbf{n}$ into $\mathbf{n}'$. From this follows, since transposition of Ω gives its inverse,

$$\mathbf{n} = \Omega^{-1}\,\mathbf{n}' = \Omega^{T}\,\mathbf{n}' \tag{6}$$

The matrix product can now be written in the more symmetric form

$$\begin{bmatrix} \gamma & -\beta\gamma\mathbf{n}^{T} \\ -\beta\gamma\mathbf{n}' & \Omega + (\gamma-1)\mathbf{n}'\mathbf{n}'^{T} \end{bmatrix} \tag{7}$$

It can now be transformed with the same rotation matrix into the left translation form

$$\begin{bmatrix} \gamma & -\beta\gamma\,\mathbf{n}'^{T} \\ -\beta\gamma\mathbf{n}' & I + (\gamma-1)\mathbf{n}'\mathbf{n}'^{T} \end{bmatrix}\begin{bmatrix} 1 & 0 \\ 0 & \Omega \end{bmatrix} \tag{8}$$

The form (7) will be taken as the *canonical form* for the product of two Lorentz transformations. It represents the most general element of the Lorentz group as may be seen as follows. Given two such matrices, the first may be put in the form (3) and the second in the form (8). Their product then involves the product of two Lorentz translations which is again a canonical matrix. Such products generate the whole Lorentz group.

Each element of the group is characterized by the angle of Ω which is additive on multiplication of the matrices.

3. The Explicit Product

The explicit product can be found by the method of Silberstein. In obvious notation the product $L_2 L_1$ is

$$\begin{bmatrix} \gamma_2 & -\beta_2\gamma_2\mathbf{n}_2^{T} \\ -\beta_2\gamma_2\mathbf{n}_2 & I + (\gamma_2-1)\mathbf{n}_2\mathbf{n}_2^{T} \end{bmatrix}\begin{bmatrix} \gamma_1 & -\beta_1\gamma_1\mathbf{n}_1^{T} \\ -\beta_1\gamma_1\mathbf{n}_1 & I + (\gamma_1-1)\mathbf{n}_1\mathbf{n}_1^{T} \end{bmatrix}$$

$$= \begin{bmatrix} 1 & 0 \\ 0 & \Omega \end{bmatrix}\begin{bmatrix} \gamma & -\beta\gamma\mathbf{n}^{T} \\ -\beta\gamma\mathbf{n} & I + (\gamma-1)\mathbf{n}\mathbf{n}^{T} \end{bmatrix} \tag{1}$$

There is found after adjustments for sign, transposition, etc.

$$\begin{aligned}
\gamma &= \gamma_1\gamma_2\,\{1 + \beta_1\beta_2\,\mathbf{n}_2^{T}\mathbf{n}_1\} \\
\beta\gamma\,\mathbf{n} &= \gamma_2\,\{(I + (\gamma_1-1)\,\mathbf{n}_1\mathbf{n}_1^{T})\,\beta_2\,\mathbf{n}_2 + \gamma_1\,\beta_1\,\mathbf{n}_1\} \\
\beta\gamma\,\Omega\mathbf{n} &= \gamma_1\,\{(I + (\gamma_2-1)\,\mathbf{n}_2\mathbf{n}_2^{T})\,\beta_1\,\mathbf{n}_1 + \gamma_2\,\beta_2\,\mathbf{n}_2\} \\
\Omega + (\gamma-1)\,(\Omega\mathbf{n})\mathbf{n}^{T} &= \beta_2\beta_1\gamma_2\gamma_1\,\mathbf{n}_2\mathbf{n}_1^{T} + (I + (\gamma_2-1)\,\mathbf{n}_2\mathbf{n}_2^{T})(I + (\gamma_1-1)\,\mathbf{n}_1\mathbf{n}_1^{T})
\end{aligned} \tag{2}$$

From the 1st and 2nd of these equations follows

$$\beta\,\mathbf{n} = \frac{(I + (\gamma_1 - 1)\,\mathbf{n}_1\mathbf{n}_1^T)\,\beta_2\,\mathbf{n}_2 + \gamma_1\beta_1\mathbf{n}_1}{\gamma_1\{1 + \beta_1\beta_2\,\mathbf{n}_1^T\mathbf{n}_2\}}$$

$$= \frac{\{\gamma_1^{-1}\,(I - \mathbf{n}_1\mathbf{n}_1^T) + \mathbf{n}_1\mathbf{n}_1^T\}\,\beta_2\,\mathbf{n}_2 + \beta_1\mathbf{n}_1}{\{1 + \beta_1\beta_2\,\mathbf{n}_1^T\mathbf{n}_2\}}$$

$$= \frac{\sqrt{(1 - \beta_1^2)}\,(I - \mathbf{n}_1\mathbf{n}_1^T)\,\beta_2\,\mathbf{n}_2 + \{\mathbf{n}_1^T\mathbf{n}_2\,\beta_2 + \beta_1\}\mathbf{n}_1}{\{1 + \beta_1\beta_2\,\mathbf{n}_1^T\mathbf{n}_2\}} \qquad (3)$$

Here the numerator is resolved into components orthogonal and parallel to $\mathbf{n}_1$ and the equation can be written, using the angle θ say between $\mathbf{n}_1$ and $\mathbf{n}_2$, as

$$\beta\,\mathbf{n} = \frac{\sqrt{(1 - \beta_1^2)}\,\beta_2 \sin\theta\,\mathbf{n}_1^{\perp} + \{\beta_2\cos\theta + \beta_1\}\mathbf{n}_1}{\{1 + \beta_1\beta_2\cos\theta\}} \qquad (4)$$

where $\mathbf{n}_1^{\perp}$ is the unit vector orthogonal to $\mathbf{n}_1$. In a similar way is found

$$\beta\,\Omega\mathbf{n} = \beta\,\mathbf{n}' = \frac{\sqrt{(1 - \beta_2^2)}\,\beta_1 \sin\theta\,\mathbf{n}_2^{\perp} + \{\beta_1\cos\theta + \beta_2\}\mathbf{n}_2}{\{1 + \beta_1\beta_2\cos\theta\}} \qquad (5)$$

* *The Einstein composition formula*: These expressions show the relation to velocity composition and there follows immediately for the magnitude squared

$$\beta^2 = \frac{(1 - \beta_1^2)\,\beta_2^2\sin^2\theta + \{\beta_2\cos\theta + \beta_1\}^2}{\{1 + \beta_1\beta_2\cos\theta\}^2}$$

$$= \frac{\beta_1^2 + 2\,\beta_1\beta_2\cos\theta + \beta_2^2 - (\beta_1\beta_2)^2\sin^2\theta}{\{1 + \beta_1\beta_2\cos\theta\}^2} \qquad (6)$$

Or in terms of velocity,

$$v^2 = \frac{v_1^2 + 2\,v_1v_2\cos\theta + v_2^2 - (v_1v_2/c)^2\sin^2\theta}{\{1 + v_1v_2/c^2.\cos\theta\}^2} \qquad (7)$$

---

* *Reference*: The calculation here is its equivalent using matrices of Silberstein's 1914 calculation using vector and dyadic notation.

4. Composition of Orthogonal Motions

The composition formulae may be simplified by taking the plane of the two velocities as the xy plane so that the z-axis then becomes redundant. The Lorentz matrices can then be written conveniently as 3 x 3 matrices transforming only the variables ct, x, y while the spatial rotation matrix Ω can be written as the 2x2 matrix

$$\Omega = \begin{bmatrix} \cos\psi & \sin\psi \\ -\sin\psi & \cos\psi \end{bmatrix} \qquad (1)$$

Ψ is the rotation angle, which is the angle Ω turns $\mathbf{n}$ through to give $\mathbf{n}'$.

* *Composition of orthogonal velocities*: This is an important special case. The velocities may be taken along the x and y axes and then introducing as before β_1, β_2, β, for the ratios v_1/c, v_2/c, v/c the Lorentz matrices will be

$$L_1 = \begin{bmatrix} \gamma_1 & -\gamma_1\beta_1 & 0 \\ -\gamma_1\beta_1 & \gamma_1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \tag{2}$$

$$L_2 = \begin{bmatrix} \gamma_2 & 0 & -\gamma_2\beta_2 \\ 0 & 1 & 0 \\ -\gamma_2\beta_2 & 0 & \gamma_2 \end{bmatrix} \tag{3}$$

The product is

$$L_2.L_1 = \begin{bmatrix} \gamma_1\gamma_2 & -\gamma_1\gamma_2\beta_1 & -\gamma_2\beta_2 \\ -\gamma_1\beta_1 & \gamma_1 & 0 \\ -\gamma_1\gamma_2\beta_2 & \gamma_1\gamma_2\beta\beta_2 & \gamma_2 \end{bmatrix} \tag{4}$$

There follow the equations

$$\begin{aligned} \gamma &= \gamma_1\gamma_2 \\ \gamma\beta\ \mathbf{n}^T &= [\gamma_1\gamma_2\beta_1, \gamma_2\beta_2] \\ \gamma\beta\,(\Omega\mathbf{n})^T &= [\gamma_1\beta_1, \gamma_1\gamma_2\beta_2] \end{aligned} \tag{5}$$

Here the value of β is given by

$$\beta^2 = \beta_1^2 + \beta_2^2/\gamma_1^2 = \beta_1^2/\gamma_2^2 + \beta_2^2 = \beta_1^2 + \beta_2^2 - \beta_1^2\beta_2^2 \tag{6}$$

The unit vectors **n**, **n'** for the two velocity compositions are

$$\begin{aligned} \mathbf{n}^T &= [\beta_1, \beta_2/\gamma_1]\,\beta^{-1} = [\beta_1, \beta_2\sqrt{(1-\beta_1^2)}]\,\beta^{-1} \\ \mathbf{n}'^T &= [\beta_1/\gamma_2, \beta_2]\,\beta^{-1} = [\beta_1\sqrt{(1-\beta_2^2)}, \beta_2]\,\beta^{-1} \end{aligned} \tag{7}$$

The resulting right hand Lorentz translation can be constructed using **n** and the product $L_2.L_1$ written as

$$\begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos\psi & -\sin\psi \\ 0 & \sin\psi & \cos\psi \end{bmatrix} \begin{bmatrix} \gamma & -\gamma\beta_1 & -\gamma(\beta_2/\gamma_1) \\ -\gamma\beta_1 & 1+(\gamma-1)(\beta_1/\beta)^2 & (\gamma-1)(\beta_1/\beta)(\beta_2/\beta\gamma_1) \\ -\gamma(\beta_2/\gamma_1) & (\gamma-1)(\beta_2/\beta\gamma_1)(\beta_1/\beta) & 1+(\gamma-1)(\beta_2/\beta\gamma_1)^2 \end{bmatrix} \tag{8}$$

Similarly the left hand Lorentz translation can be constructed using **n'** and the product written

$$\begin{bmatrix} \gamma & -\gamma(\beta_1/\gamma_2) & -\gamma\beta_2 \\ -\gamma(\beta_1/\gamma_2) & 1+(\gamma-1)(\beta_1/\beta\gamma_2)^2 & (\gamma-1)(\beta_1/\beta\gamma_2)(\beta_2/\beta) \\ -\gamma\beta_2 & (\gamma-1)(\beta_2/\beta)(\beta_1/\beta\gamma_2) & 1+(\gamma-1)(\beta_2/\beta)^2 \end{bmatrix} \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos\psi & -\sin\psi \\ 0 & \sin\psi & \cos\psi \end{bmatrix} \tag{9}$$

The corresponding representation of $L_1 L_2$ is found by transposition which interchanges the Lorentz matrices and replaces Ψ by $-\Psi$.

5. Rotation Angle for Orthogonal Motions

The rotation angle Ψ may be determined by forming scalar and vector products of **n** and **n'** which give $\cos\Psi$ and $\sin\Psi$. In the case of composition of orthogonal motions there is found in this way, using values of **n** and **n'** found in the previous section,

$$\begin{aligned} \cos\Psi &= (\sqrt{(1-\beta_2^2)}\,\beta_1^2 + \sqrt{(1-\beta_1^2)}\,\beta_2^2)/\beta^2 = (\gamma_2^{-1}\beta_1^2 + \gamma_1^{-1}\beta_2^2)/\beta^2 \\ \sin\Psi &= \beta_1\beta_2\,(1-\sqrt{(1-\beta_1^2)(1-\beta_2^2)})/\beta^2 = \beta_1\beta_2\,(1-\gamma_1^{-1}\gamma_2^{-1})/\beta^2 \\ \tan\Psi &= \beta_1\beta_2\,(\gamma_1\gamma_2-1)/(\gamma_1\beta_1^2+\gamma_2\beta_2^2) \end{aligned} \tag{1}$$

These may be expressed in various ways by algebraic transformation e.g.

$$\begin{aligned} \cos\Psi &= (\gamma_1+\gamma_2)(1-\gamma_1\gamma_2)/\beta^2 = (\gamma_1+\gamma_2)/(1+\gamma_1\gamma_2) \\ \sin\Psi &= \beta_1\beta_2/(1+\gamma_1^{-1}\gamma_2^{-1}) = \beta_1\gamma_1\beta_2\gamma_2/(1+\gamma_1\gamma_2) \\ \tan\Psi &= \beta_1\gamma_1\beta_2\gamma_2/(\gamma_1+\gamma_2) \end{aligned} \tag{2}$$

Corresponding formulae may be given in terms of the velocities v_1, v_2, e.g.

$$\cos\Psi = \frac{v_1^2\sqrt{(1-v_2^2/c^2)} + v_2^2\sqrt{(1-v_1^2/c^2)}}{v_1^2+v_2^2-(v_1v_2/c)^2} \tag{3}$$

$$\sin\Psi = \frac{v_1v_2\,[1-\sqrt{(1-v_1^2/c^2)}\sqrt{(1-v_2^2/c^2)}]}{v_1^2+v_2^2-(v_1v_2/c)^2}$$

$$= \frac{v_1v_2}{c^2\,[1+\sqrt{(1-v_1^2/c^2)}\sqrt{(1-v_2^2/c^2)}]} \tag{4}$$

$$\tan\Psi = \frac{v_1v_2\,[1-\sqrt{(1-v_1^2/c^2)}\sqrt{(1-v_2^2/c^2)}]}{v_1^2\sqrt{(1-v_2^2/c^2)}+v_2^2\sqrt{(1-v_1^2/c^2)}} \tag{5}$$

* *Half-angle formulae*: The half-angle formulae for rotation angle Ψ take a simpler form. They appear to have some importance in the theory. They may be found from:

$$\begin{aligned} \cos^2\Psi/2 &= \frac{1+\cos\Psi}{2} = \frac{(\gamma_1+1)(\gamma_2+1)}{2(1+\gamma_1\gamma_2)} \\ \sin^2\Psi/2 &= \frac{1-\cos\Psi}{2} = \frac{(\gamma_1-1)(\gamma_2-1)}{2(1+\gamma_1\gamma_2)} \\ \tan^2\Psi/2 &= \frac{\sin^2\Psi/2}{\cos^2\Psi/2} = \frac{(\gamma_1-1)(\gamma_2-1)}{(\gamma_1+1)(\gamma_2+1)} \end{aligned} \tag{6}$$

From the last follows a formula due to Liebmann (quoted by Varićak 1912)

$$\cot \Psi/2 = \frac{\sqrt{(\gamma_1 + 1)(\gamma_2 + 1)}}{\sqrt{(\gamma_1 - 1)(\gamma_2 - 1)}} \tag{7}$$

6. The Thomas Precession

The Thomas precession is a well known rotational effect occurring whenever acceleration α is in a different direction to velocity so that the velocities v, $v + \delta v$ at successive instants t, $t + \delta t$ do not have the same direction. The combination of the Lorentz matrices for these velocities results in an infinitesimal infinitesimal rotation $\delta\Psi$. One method of calculating this is by the formulae which have been derived for combination of orthogonal velocities.

If vector velocities **v** and **δv** are inclined at an angle θ, the increment **δv** has components parallel and orthogonal to **v** of $\delta v \cos\theta$, $\delta v \sin\theta$. Being infinitesimal, their effects may be superimposed, and to the first order of small quantities, the resulting infinitesimal rotation $\delta\Psi$ arises only from the orthogonal component. So the rotation angle may be found from the previous formula

$$\sin \Psi = \frac{v_1 v_2}{c^2 \{1 + \sqrt{(1 - v_1^2/c^2)}\sqrt{(1 - v_2^2/c^2)}\}} \tag{1}$$

On setting

$$v_1 = v,\ v_2 = \delta v \sin\theta = \alpha\, \delta t \sin\theta,\ \Psi = \delta\Psi \tag{2}$$

the following approximations will hold to first order:

$$\sqrt{(1 - v_1^2/c^2)} \approx \sqrt{(1 - v^2/c^2)} = \gamma^{-1},$$
$$\sqrt{(1 - v_2^2/c^2)} \approx 1 \tag{3}$$

The angular velocity relative to the observer is

$$\frac{d\Psi}{dt} = \frac{v\,\alpha \sin\theta}{c^2 \{1 + \sqrt{(1 - v^2/c^2)}\}} = \frac{\{1 - \sqrt{(1 - v^2/c^2)}\}\, v\,\alpha \sin\theta}{v^2} \tag{4}$$

Relative to the moving point it is

$$\frac{d\Psi}{d\tau} = \frac{\{1 - \sqrt{(1 - v^2/c^2)}\}\, v\,\alpha \sin\theta}{v^2 \sqrt{(1 - v^2/c^2)}} = \{\gamma - 1\} \frac{v\,\alpha \sin\theta}{v^2} \tag{5}$$

This can be written as the vector equation

$$\frac{d\mathbf{\Psi}}{d\tau} = (\gamma - 1)\, \frac{\mathbf{v} \times \boldsymbol{\alpha}}{v^2} \tag{6}$$

The rotation is about an axis perpendicular to **v** and **α** and in the direction of **v x α**.

* *Approximation for v<<c*: If the velocity v is small compared with that of light,

$$\delta\Psi \approx \sin\delta\Psi = \frac{v_1 v_2}{c^2\{1+\sqrt{(1-v_1^2/c^2)}\sqrt{(1-v_2^2/c^2)}\}} \approx \frac{v_1 v_2}{2c^2} = \frac{v\,\delta v \sin\theta}{2c^2} \tag{7}$$

resulting in

$$\frac{d\Psi}{dt} = \frac{v\,a \sin\theta}{2c^2} \tag{8}$$

$$\frac{d\mathbf{\Psi}}{d\tau} = \frac{\mathbf{v} \times \mathbf{a}}{2c^2} \tag{9}$$

Note: The Thomas rotation was encountered in connexion with the accelerated motion of an electron in an electric field where the formula for spin of Goudschmidt and Uhlenbeck was corrected by Thomas (1926, 1927). Thomas' first paper gave the approximate formula, the more accurate formula being given in his second paper. It is interesting that Borel had previously deduced in 1913 on purely mathematical grounds that such an effect would occur. Subsequent to Thomas' work the spatial rotation associated with the composition of two general Lorentz translations also became known as the Thomas rotation even though the Thomas precession is only a special case. When, at a later period, the same phenomenon found application in quantum mechanics and particle physics, the name 'Wigner rotation' also came into use for the general rotation.

CHAPTER 3 – Sommerfeld's Spherical Theory

1. The Lorentz Transformation as Rotation.

In his fundamental 1909 paper 'On the composition of velocities', Sommerfeld aimed to show how the space-time view of Minkowski, then recently introduced, could be of real use to physicists. His spherical interpretation of Einstein's composition formula led on directly to the hyperbolic theory.

As previously described, Minkowski had, In his investigation of Maxwell's equations, somewhat incidentally, represented the Lorentz transformation as a Euclidean rotation

$$\begin{aligned} x' &= x \cos\varphi + ict \sin\varphi \\ ict' &= -x \sin\varphi + ict \cos\varphi \end{aligned} \qquad (1)$$

The purely imaginary angle φ is defined by

$$\tan\varphi = i\, v/c \qquad (2)$$

implying

$$\cos\varphi = \frac{1}{\sqrt{(1 - v^2/c^2)}} = \gamma \qquad \sin\varphi = \frac{i\,(v/c)}{\sqrt{(1 - v^2/c^2)}} = i\,\beta\gamma \qquad (3)$$

Sommerfeld pointed out that this representation simplifies the composition rule for rectilinear motion since the result of two successive Lorentz transformations of angles φ_1, φ_2 is the Lorentz transformation with angle $\varphi_1 + \varphi_2$ given by

$$iv/c = \tan(\varphi_1 + \varphi_2) = \frac{\tan\varphi_1 + \tan\varphi_2}{1 - \tan\varphi_1 \tan\varphi_2} = \frac{iv_1/c + iv_2/c}{1 - iv_1/c\, iv_2/c} \qquad (4)$$

There follows the composition rule

$$v = \frac{v_1 + v_2}{1 + v_1 v_2/c^2} \qquad (5)$$

This new method of deriving the composition rule soon came into general use and was, for example, used by Einstein in his 1921 Princeton lectures replacing his earlier method. It is now well known. Not so well known however, is the generalization of this idea to the non-rectilinear case introduced by Sommerfeld in his 1909 paper and subsequent writings.

Reference: Sommerfeld A: 'Über die Zusammensetzung der Geschwindigkeiten' *Phys.Z.* 1909 826-829.

2. Non-commutativity of Velocity Addition

Einstein's 1905 derivation of the composition rule gave the magnitude of the resultant of two velocities but had said nothing about its direction. Sommerfeld attempted to clarify this situation by combining two orthogonal velocities

$$\mathbf{v}_1 = (v_1, 0), \quad \mathbf{v}_2 = (0, v_2) \tag{1}$$

This can be done in two possible ways - $\mathbf{v}_1$ followed by $\mathbf{v}_2$ and $\mathbf{v}_2$ followed by $\mathbf{v}_1$. He found, in agreement with Einstein's calculation (cf chapter 1), for the resultant velocities corresponding to these two ways the values

$$(v_1, v_2\sqrt{(1 - v_1^2/c^2)}), \quad (v_1\sqrt{(1 - v_2^2/c^2)}, v_2) \tag{2}$$

These have the same magnitude squared

$$v^2 = v_1^2 + v_2^2 - (v_1 v_2/c)^2 \tag{3}$$

which can be written in either of two ways corresponding to the two resultants:

$$v^2 = v_1^2 + v_2^2 (1 - v_1^2/c^2) = v_1^2 (1 - v_2^2/c^2) + v_2^2 \tag{4}$$

From these are found Pythagoras formulae corresponding to the figure below. The resultant velocities are represented by lines AC and C'A' of equal length.

Fig: Non-commutativity of velocity composition (Cartesian form)

Multiplication of the transverse velocity components by contraction factors results in failure of the rectangular figure to close giving rise to what became known as non-commutativity of velocity addition. The angle Ψ between the resultants, which was already determined in the last chapter, is easily also found from this diagram by taking scalar and vector products of the vectors (2).

As seen in the last chapter, composition of the Lorentz translations results in a rotation through the angle Ψ. The curious consequence of this is apparently to make an interchange of directions so that $\mathbf{v}_1$ followed by $\mathbf{v}_2$ results, not in vector AC, but in C'A' - this vector turned through angle Ψ. It is similar for $\mathbf{v}_2$ followed by $\mathbf{v}_1$.

3. The Spherical Representation

Sommerfeld explained noncommutativity of velocity addition as arising from addition of displacements on a sphere determined by the Minkowski angles.

In the case of addition of orthogonal velocities, the relation between the velocities v_1, v_2 and their resultant v may be written

$$(1 - v^2/c^2) = (1 - v_1^2/c^2)\,(1 - v_2^2/c^2) \qquad (1)$$

This gives

$$\frac{1}{\sqrt{(1 - v^2/c^2)}} = \frac{1}{\sqrt{(1 - v_1^2/c^2)}}\,\frac{1}{\sqrt{(1 - v_2^2/c^2)}} \qquad (2)$$

By using Minkowski angles φ, φ_1, φ_2, corresponding to v, v_1, v_2, the equation becomes

$$\cos\varphi = \cos\varphi_1 \cos\varphi_2 \qquad (3)$$

which is the Pythagoras formula for the right angled spherical triangle the Minkowski angles project on the surface of a sphere. This spherical form is equivalent to the Cartesian form since the algebra is reversible. The Minkowski angles are all purely imaginary as can be seen from (2) since all factors exceed unity

As in the Cartesian case the question of non-commutativity arises and there are two triangles according to whether φ_1 or φ_2 is first. Sommerfeld represented the two spherical triangles diagrammatically in the plane the sides of these triangles being proportional to Minkowski angles. The figure below shows these triangles, denoted ABC, A'B'C' the right angle being at vertices B, B'.

Fig: Non-commutativity of velocity composition (spherical form)

Unlike the Cartesian case, the triangles ABC, A'B'C' are now congruent (although reversed) and overlap instead of being separated. But they still do not add to form a rectangular figure because of spherical geometry which thus gives a natural explanation of the noncommutativity. From this example Sommerfeld concluded:

> *"For the combination of velocities in relativity theory there is valid, not formulae of the plane, but instead spherical trigonometry (with imaginary sides.)"*

4. Spherical Form of the Einstein Composition Formula

Extending these ideas, Sommerfeld derived the general composition law for inclined velocities. The Minkowski angle φ of the resultant velocity v is given by vector addition of the arcs on a sphere of the Minkowski angles φ_1, φ_2 for v_1, v_2 so that by the spherical cosine rule:

$$\cos\varphi = \cos\varphi_1 \cos\varphi_2 + \sin\varphi_1 \sin\varphi_2 \cos(\pi - \theta) \tag{4}$$

where θ is the angle of inclination of velocities v_1, v_2. This is

$$\cos\varphi = \cos\varphi_1 \cos\varphi_2 - \sin\varphi_1 \sin\varphi_2 \cos\theta \tag{5}$$

Changing from Minkowski angles to velocities gives

$$\frac{1}{\sqrt{(1 - v^2/c^2)}} = \frac{1}{\sqrt{(1 - v_1^2/c^2)}\sqrt{(1 - v_2^2/c^2)}} - \frac{(iv_1/c)}{\sqrt{(1 - v_1^2/c^2)}} \frac{(iv_2/c)}{\sqrt{(1 - v_2^2/c^2)}} \cos\theta \tag{6}$$

$$= \frac{(1 + v_1 v_2/c^2 \cos\theta)}{\sqrt{(1 - v_1^2/c^2)}\sqrt{(1 - v_2^2/c^2)}} \tag{7}$$

Inversion and squaring results in

$$(1 - v^2/c^2) = \frac{(1 - v_1^2/c^2)(1 - v_2^2/c^2)}{(1 + v_1 v_2/c^2 \cos\theta)^2} \tag{8}$$

Then solving for v gives Einstein's composition law

$$v = \frac{\sqrt{\{v_1^2 + v_2^2 + 2 v_1 v_2 \cos\theta - (v_1 v_2/c \sin\theta)^2\}}}{1 + (v_1 v_2/c^2)\cos\theta} \tag{9}$$

The algebra here is reversible so that starting from the composition formula the spherical cosine rule can be deduced.

5. Spherical Excess and Rotation Angle

As later described by Sommerfeld (1931), the spherical representation gives a geometrical method for the determination of the rotation angle Ψ. Reconsider the figure illustrated below.

Fig: Rotation angle (spherical form)

The rotation angle is the angle between AC and C'A' which is seen to be

$$\Psi = (A + B + C) - \pi \tag{1}$$

Ψ is the spherical excess E of either triangle ABC or A'B'C' and equality (1) is not dependent on the triangles being right angled. By using its interpretation as spherical excess, the determination of the rotation angle is reduced to the purely trigonometrical problem of finding the spherical excess of a triangle.

Sommerfeld used this method to find the rotation angle for velocities at right angles and applied the result to the Thomas rotation. To get the spherical excess E, he used the formula from spherical trigonometry

$$\sin E = \frac{\sin \varphi_1 \sin \varphi_2}{1 + \cos \varphi_1 \cos \varphi_2} \tag{2}$$

Here φ_1, φ_2 are the Minkowski angles corresponding to the two velocities. Then on going back to velocities he found the formula already derived in chapter 2:

$$\sin \Psi = \frac{v_1 v_2}{c^2} \frac{1}{\{1 + \sqrt{(1 - v_1^2/c^2)}\sqrt{(1 - v_2^2/c^2)}\}} \approx \frac{v_1 v_2}{2 c^2} \tag{3}$$

From which easily follows, as before, the formula for Thomas rotation.

* *Note*: Sommerfeld did not give details of the derivation of the relation (2) dismissing it as elementary. Though elementary, the proof is somewhat tricky. It needs the use of sine, cosine and cotangent formulae in the forms

$$\sin A = \sin \varphi_1 / \sin \varphi\,, \quad \sin C = \sin \varphi_2 / \sin \varphi$$
$$\cos \varphi = \cos \varphi_1 \cos \varphi_2$$
$$\cot A \cot C = \cos \varphi$$

Then, since B is $\pi/2$,

$$\begin{aligned}
\sin E &= \sin (A + C - \pi/2) \\
&= -\cos (A+C) \\
&= -\cos A \cos C + \sin A \sin C \\
&= \sin A \sin C\,(1 - \cot A \cot C) \\
&= (\sin \varphi_1 / \sin \varphi)(\sin \varphi_2 / \sin \varphi)(1 - \cos \varphi) \\
&= \sin \varphi_1 \sin \varphi_2\,(1 - \cos \varphi) / (1 - \cos^2 \varphi) \\
&= \sin \varphi_1 \sin \varphi_2 / (1 + \cos \varphi) \\
&= \sin \varphi_1 \sin \varphi_2 / (1 + \cos \varphi_1 \cos \varphi_2) \qquad (4)
\end{aligned}$$

Quod erat demonstradum!

6. Central Projection and the Contraction Factor

An interesting aspect of the Sommerfeld representation, which Sommerfeld himself did not analyse in detail is its relation with central projection of the sphere on to a tangential plane. Here is seen the possiblity, through non-Euclidean geometry, of explaining the contraction so typical of relativistic formulae. At the same time there is revealed a shortcoming of the spherical representation.

The relation between velocities and their Minkowski angles, which may be written

$$v = R \tan \varphi \qquad (1)$$

with R equal to c/i (= – ic), suggests the geometrical representation shown in the first figure below; it leads to the idea of projection of the spherical triangle ABC on to another triangle $A_1B_1C_1$ in the tangential plane at one vertex (A in the second figure)

Fig. Geometric meaning of Minkowski angle

Fig. Central projection of a right--angled spherical triangle.

This geometrical representation of course ignores the fact that both R and φ are imaginary and R is even negative. Such a figure is only permissible in the spirit of the Sommerfeld representation which ignores all problems associated with geometrical representation of complex quantities in the attempt to provide an intuitive picture to aid thinking. The ultimate justification for doing this is that the resulting relationships become strictly valid in the hyperbolic version considered below.

In this representation the tangential sides A_1B_1, A_1C_1, B_1C_1 are

$$R \tan \varphi_1 = v_1$$
$$R \tan \varphi = v$$
$$(R \sec \varphi_1) \tan \varphi_2 = (R \tan \varphi_2) \sec \varphi_1 = v_2 \sqrt{(1 - v_1^2/c^2)} \qquad (2)$$

The spherical triangle and its projection are shown below together for comparison.

ig. The spherical triangle

Fig. The projected triangle

The Cartesian components v_x, v_y of the resultant velocity **v** are A_1B_1, B_1C_1 given by

$$v_x = R \tan \varphi_1 = v_1$$
$$v_y = (R \tan \varphi_2) \sec \varphi_1 = v_2 \sqrt{(1 - v_1^2/c^2)} \qquad (3)$$

This explains the existence of the contraction factor affecting transverse velocity.

While this calculation and its diagrammatic illustration are in principle correct, a contradiction arises from the geometrical representation. The figure above shows the third side OB_1 greater than OA_1 after multiplication by the factor $\sec \varphi_1$ whereas, because φ_1 is purely imaginary, $\sec \varphi_1$ is less than unity and so OB_1 should be less than OA_1.

The contradiction can be avoided by adhering to the following derivation which however loses the geometrical picture. From the basic equations of spherical trigonometry applied to the right-angled spherical triangle ABC we get

$$\begin{aligned} \tan\varphi_1 &= \tan\varphi \cos A \\ \sin\varphi_2 &= \sin\varphi \sin A \\ \cos\varphi &= \cos\varphi_1 \cos\varphi_2 \end{aligned} \tag{4}$$

From the second and third of these equations follows

$$\tan\varphi \sin A = \tan\varphi_2 \sec\varphi_1 \tag{5}$$

so that the Cartesian components are, using these equations,

$$\begin{aligned} v_x &= v\cos A = R\tan\varphi \cos A = R\tan\varphi_1 = v_1 \\ v_y &= v\sin A = R\tan\varphi \sin A = R\tan\varphi_2 \sec\varphi_1 = v_2\sqrt{(1 - v_1^2/c^2)} \end{aligned} \tag{6}$$

CHAPTER 4 – The Hyperbolic Theory

1. Rapidity

The basic quantity of the hyperbolic theory is the *rapidity* w defined in terms of the velocity by

$$\text{th } w = v/c \tag{1}$$

the principal value of the inverse hyperbolic tangent being used for the determination of w from this equation. Corresponding to any value of v less in magnitude to c this equation determines a value of w lying in the range $-\infty < w < \infty$. Transforming the Minkowski rotational representation and its inverse

$$\begin{aligned} x' &= x \cos\varphi + ict \sin\varphi \\ ict' &= -x \sin\varphi + ict \cos\varphi \end{aligned} \qquad \begin{aligned} x &= x' \cos\varphi - ict' \sin\varphi \\ ict &= x' \sin\varphi + ict' \cos\varphi \end{aligned} \tag{2}$$

by setting φ to be iw and using the identities

$$\begin{aligned} \cos\varphi &= \cos iw = \text{ch } w \\ \sin\varphi &= \sin iw = i \text{ sh } w \end{aligned} \tag{3}$$

there arises the symmetric transformation and its inverse

$$\begin{aligned} ct' &= ct \text{ ch } w - x \text{ sh } w \\ x' &= -ct \text{ sh } w + x \text{ ch } w \end{aligned} \qquad \begin{aligned} ct &= ct' \text{ ch } w + x' \text{ sh } w \\ x &= ct' \text{ sh } w + x' \text{ ch } w \end{aligned} \tag{4}$$

which is the representation in terms of rapidity. Note that from (1) follows

$$\text{ch } w = \frac{1}{\sqrt{(1 - v^2/c^2)}} \qquad \text{sh } w = \frac{(v/c)}{\sqrt{(1 - v^2/c^2)}} \tag{5}$$

* *Additivity*: The characteristic property of rapidity is its additivity for velocity composition. This additivity is obvious from the relation with Minkowski's imaginary Euclidean form but can also be seen directly from the identity

$$\text{th } (w_1 + w_2) = \frac{\text{th } w_1 + \text{th } w_2}{1 + \text{th } w_1 \text{ th } w_2} \tag{6}$$

which immediately results in the composition law

$$v = \frac{v_1 + v_2}{1 + v_1 v_2/c^2} \tag{7}$$

for the velocity v corresponding to rapidity $w_1 + w_2$ so that for the rapidities w_1, w_2, w corresponding to v_1, v_2, v it is true that

$$w = w_1 + w_2 \tag{8}$$

* *Matrix representation*: In terms of rapidity the Lorentz translation matrix takes the symmetric form

$$L(w) = \begin{bmatrix} \mathrm{ch}\,w & -\mathrm{sh}\,w \\ -\mathrm{sh}\,w & \mathrm{ch}\,w \end{bmatrix} \tag{9}$$

with inverse

$$L(-w) = \begin{bmatrix} \mathrm{ch}\,w & \mathrm{sh}\,w \\ \mathrm{sh}\,w & \mathrm{ch}\,w \end{bmatrix} \tag{10}$$

The multiplication law is expressed by the equations

$$\begin{bmatrix} \mathrm{ch}(w_1+w_2) & -\mathrm{sh}(w_1+w_2) \\ -\mathrm{sh}(w_1+w_2) & \mathrm{ch}(w_1+w_2) \end{bmatrix} = \begin{bmatrix} \mathrm{ch}\,w_2 & -\mathrm{sh}\,w_2 \\ -\mathrm{sh}\,w_2 & \mathrm{ch}\,w_2 \end{bmatrix} \begin{bmatrix} \mathrm{ch}\,w_1 & -\mathrm{sh}\,w_1 \\ -\mathrm{sh}\,w_1 & \mathrm{ch}\,w_1 \end{bmatrix} \tag{11}$$

$$L(w_1+w_2) = L(w_1)\,L(w_2) \tag{12}$$

This semigroup property makes possible the exponential representation

$$L(w) = \exp Kw = I + Kw + \frac{(Kw)^2}{2!} + \frac{(Kw)^3}{3!} + \,. \tag{13}$$

where K is the infinitesimal generator

$$K = \begin{bmatrix} 0 & -1 \\ -1 & 0 \end{bmatrix} \tag{14}$$

---

* *Historical note*: Minkowski (1908) defined a quantity ψ satisfying (in modern notation)

$$\mathrm{th}\,\psi = v/c$$

Here ψ is the rapidity but Minkowski only used it to define his imaginary angle φ as equal to $i\psi$ and then made no further use of it. Varićak (1910 etc) used the notation w and described its properties. Then it was independently defined by Robb in 1911 who gave it the name rapidity. It has since been quite commonly used for representation of the Lorentz transformation even though the Lorentz transformation loses the intuitive appeal of the imaginary rotational form when written in this way. Notably, Whittaker, in his well known historical book (1910 etc), used the rapidity consistently. Various notations have been used instead of w including the original Minkowski ψ. It has been commonly regarded as an arbitrary mathematical parameter without any special physical significance

2. The Hyperbolic Triangle Law for Velocity Addition.

Since the early days of the theory of hyperbolic geometry it has been realized that the trigonometric formulae can be obtained from those of spherical trigonometry by using imaginary angles or equivalently by using a sphere of imaginary radius. It is therefore a natural step to reinterpret the Sommerfeld theory in terms of hyperbolic geometry. Since the Sommerfeld theory is based on the use of imaginary angles and radii, the change to the hyperbolic form goes from imaginary to real form. This change was made by Varićak in 1910 soon after the appearance of Sommerfeld's 1909 paper. Then followed independent work by a few others, e.g. Robb (1911) and Borel (1913, 1914), also arriving at a hyperbolic representation.

The change from the spherical to the hyperbolic form was mathematically a small step but it was of considerable importance in setting the theory on its correct path: establishing the physical reality of hyperbolic geometry and its central significance for the accurate statement of the Principle of Relativity.

Substituting variables iw for angles φ in Sommerfeld's cosine formula leads to an equation which can be written as the cosine rule in hyperbolic space:

$$\text{ch } w = \text{ch } w_1 \text{ ch } w_2 - \text{sh } w_1 \text{ sh } w_2 \cos(\pi - \theta) \tag{1}$$

This equation is illustrated in the diagram below by the triangle ABC with slightly inwardly curving sides to suggest the negative curvature.

Fig. A triangle of hyperbolic rapidities.

The direct derivation of formula (1) starting from Einstein's composition rule is:

$$v^2 = \frac{\{v_1^2 + v_2^2 + 2\, v_1 v_2 \cos\theta - (v_1 v_2/c \sin\theta)^2\}}{1 + (v_1.v_2/c^2)\cos\theta} \tag{2}$$

$$(1 - v^2/c^2) = \frac{(1 - v^2/c^2)(1 - v^2/c^2)}{(1 + v_1 v_2/c^2 \cos\theta)^2} \tag{3}$$

$$\frac{1}{\sqrt{(1 - v^2/c^2)}} = \frac{1}{\sqrt{(1 - v^2/c^2)}}\frac{1}{\sqrt{(1 - v^2/c^2)}} + \frac{(v_1/c)}{\sqrt{(1 - v^2/c^2)}}\frac{(v_2/c)}{\sqrt{(1 - v^2/c^2)}}\cos\theta \tag{4}$$

Formula (1) results on substitution of hyperbolic functions.

* *Historical note*:
1) The transition from spherical to hyperbolic trigonometry by the use of complex quantities is due to Taurinus (1826) and antedates much other work on hyperbolic geometry. See J. Gray: *Ideas of Space*, 1969 Oxford Univ. Press. The fact used in Varićak's transformation of the Sommerfeld form is that a pseudospherical sphere of imaginary radius is identical with a hyperboloid of revolution.
2) See the references to Varićak, Robb and Borel in the general bibliography. Vladimir Varićak (1865-1942) was professor of mathematics at Zagreb University. His biography was given by Kurepa (1965). Further contributions were made by Lewis & Tolman (1909), Ogura (1913), LeRoux(1922), Milne(1934), Karapetoff (1944), Patria (1956), Smorodinski (1963,1964). An extensive review has been given by Scott-Walker (1996, 1999)

3. Cartesian Projection from Hyperbolic Space

The analogue of central projection of a sphere on to a tangential plane exists in hyperbolic geometry, the equivalent of the tangential plane at a point being a Euclidean plane called the *limiting plane*. As a result, many trigonometric formulae for hyperbolic space can be derived by projection in a similar way to the spherical case though the procedure is not intuitive.

The equation corresponding to the imaginary R tan φ is

$$v = c \operatorname{th} w \tag{1}$$

is regarded as showing velocity as a Euclidean projection of the rapidity w om hyperbolic space of negative radius of curvature c.

Considering again the composition of two velocities v_1, v_2 at right angles, where a hyperbolic triangle ABC with a right angle at B is projected on to a plane triangle $A_1B_1C_1$ tangential at $A=A_1$. Transcribing the equations of the spherical case gives the to the sides a_1, b_1, c_1 of the Euclidean triangle $A_1B_1C_1$ the values

$$\begin{aligned} a_1 &= c \operatorname{th} w_2 \operatorname{sech} w_1 \\ b_1 &= c \operatorname{th} w \\ c_1 &= c \operatorname{th} w_1 \end{aligned} \tag{2}$$

The hyperbolic triangle ABC and its Cartesian projection $A_1B_1C_1$ are as illustrated below

Fig: The right-angled hyperbolic triangle.

Fig: The projected triangle
(In terms of rapidities)

The sides of the projected triangle may alternatively be found using trigonometric formulae for a hyperbolic triangle given in the mathematical appendix.

$$\begin{aligned} \text{th } w_1 &= \text{th } w \cos A \\ \text{sh } w_2 &= \text{sh } w \sin A \\ \text{ch } w &= \text{ch } w_1 \text{ ch } w_2 \end{aligned} \tag{3}$$

From the second and third equation follows

$$\text{th } w \sin A = \text{th } w_2 \text{ sech } w_1 \tag{4}$$

The Cartesian velocity components v_x, v_y represented by sides c_1, a_1 are then

$$\begin{aligned} v_x &= c \text{ th } w \cos A = c \text{ th } w_1 = v_1 \\ v_y &= c \text{ th } w \sin A = c \text{ th } w_2 \text{ sech } w_1 = v_2 \sqrt{[1-(v_1/c)^2]} \end{aligned} \tag{5}$$

as before. Here is seen the contraction factor in the transverse velocity. See the figure below.

Fig: The projected triangle.
(In terms of velocities)

4. Hyperbolic Deficiency and Rotation Angle

The interpretation of noncommutativity in hyperbolic geometry corresponding to that of Sommerfeld for the spherical case is shown in the figure below.

Fig: Non-commutativity (hyperbolic case)

Here the congruent triangles ABC, A'B'C' no longer overlap resulting in a difference in sign between this and the spherical case. As indicated by the figure, the rotation angle Ψ is the hyperbolic deficiency D of the triangle ABC

$$\Psi = \pi - (A+B+C) = D \tag{1}$$

* *Calculation of rotation angle by trigonometry*: The equality of rotation angle Ψ with deficiency D reduces determination of rotation angle to a trigonometrical problem of finding the deficiency of a triangle.

EXAMPLE 1: Two velocities at right angles.
The analogue of Sommerfeld's formula proved in the last chapter is

$$\sin D = \frac{\operatorname{sh} w_1 \operatorname{sh} w_2}{1 + \operatorname{ch} w_1 \operatorname{ch} w_2} \tag{2}$$

and it may be proved in a similar way merely transposing from spherical to hyperbolic form, replacing E by –D and φ_1, φ_2 by iw_1, iw_2.

* *Hyperbolic form of Liebmann's half-angle formula*: From Sommerfeld's formula may easily be deduced the Liebmann formula already proved in chapter 2.

$$\sin D = \frac{\sqrt{(\operatorname{ch} w_1^2 - 1)(\operatorname{ch} w_2^2 - 1)}}{(1 + \operatorname{ch} w_1 \operatorname{ch} w_2)} \tag{3}$$

$$\cos D = \sqrt{(1 - \sin^2 D)} = \frac{(\operatorname{ch} w_1 + \operatorname{ch} w_2)}{(1 + \operatorname{ch} w_1 \operatorname{ch} w_2)} \tag{4}$$

$$\cos D + 1 = \frac{(\operatorname{ch} w_1 + 1)(\operatorname{ch} w_2 + 1)}{(1 + \operatorname{ch} w_1 \operatorname{ch} w_2)} \tag{5}$$

From this follows the required result:

$$\cot D/2 = \frac{\cos D + 1}{\sin D} = \frac{(\mathrm{ch}\, w_1 + 1)(\mathrm{ch}\, w_2 + 1)}{(\mathrm{ch}\, w_1 - 1)(\mathrm{ch}\, w_2 - 1)} = \frac{(\gamma_1 + 1)(\gamma_2 + 1)}{(\gamma_1 - 1)(\gamma_2 - 1)} \tag{6}$$

Now for any rapidity w

$$\frac{\gamma + 1}{\gamma - 1} = \frac{\mathrm{ch}\, w + 1}{\mathrm{ch}\, w - 1} = \frac{2\, \mathrm{ch}^2(w/2)}{2\, \mathrm{sh}^2(w/2)} = \coth^2 (w/2) \tag{7}$$

So the result may also be written in the hyperbolic form (Varićak 1912).

$$\cot D/2 = \coth (w_1/2) \coth (w_2/2) \tag{8}$$

EXAMPLE 2 Two velocities inclined at an angle.

The formula for rotation angle is

$$\cot \Psi/2 = \frac{C + \cos \theta}{\sin \theta} \tag{9}$$

θ being angle of inclination of velocities, and C the constant

$$C = \frac{(\gamma_1 + 1)(\gamma_2 + 1)}{(\gamma_1 - 1)(\gamma_2 - 1)} = \coth (w_1/2) \coth (w_2/2) \tag{10}$$

For orthogonal velocities, $\cos \theta = 0$, $\sin \theta = 1$ and the Liebmann formula.follows

The derivation is immediate from transcribing a formula of Lagrange for spherical excess (see the mathematical appendix). The hyperbolic form of this formula is

$$\cot (D/2) = \frac{\mathrm{ch}\, (w_1/2)\, \mathrm{ch}\, (w_2/2) + \mathrm{sh}\, (w_1/2)\, \mathrm{sh}\, (w_2/2) \cos \theta}{\mathrm{sh}\, (w_1/2)\, \mathrm{sh}\, (w_2/2) \sin \theta} \tag{11}$$

On division of numerator and denominator by the sinh half angles, there results formula (9). It may be transformed to the following symmetric form (see mathematical appendix)

$$\cot D/2 = \frac{\sqrt{(1 - \mathrm{ch}^2 w_1 - \mathrm{ch}^2 w_2 - \mathrm{ch}^2 w_3 + 2\, \mathrm{ch}\, w_1\, \mathrm{ch}\, w_2\, \mathrm{ch}\, w_3)}}{1 + \mathrm{ch}\, w_1 + \mathrm{ch}\, w_2 + \mathrm{ch}\, w_3} \tag{12}$$

From there it is it transforms to the symmetrical formulae often quoted in the particle physics literature:

$$\sin \frac{D}{2} = \frac{1 + \mathrm{ch}\, w_1 + \mathrm{ch}\, w_2 + \mathrm{ch}\, w_3}{(\mathrm{ch}\, w_1/2)\, (\mathrm{ch}\, w_2/2)\, (\mathrm{ch}\, w_3/2)} \tag{13}$$

$$\cos \frac{D}{2} = \frac{\sqrt{(1 - \mathrm{ch}^2 w_1 - \mathrm{ch}^2 w_2 - \mathrm{ch}^2 w_3 + 2\, \mathrm{ch}\, w_1\, \mathrm{ch}\, w_2\, \mathrm{ch}\, w_3)}}{4\, (\mathrm{ch}\, w_1/2)\, (\mathrm{ch}\, w_2/2)\, (\mathrm{ch}\, w_3/2)} \tag{14}$$

* *Note*: The value of Ψ given by (10) was first given, using spinors, by van Wyk (1984) and, apparently using Silberstein's method, by Ben-Menahem (1985). Subsequently many papers have been devoted to its derivation by various methods. The present one by hyperbolic trigonometry was given by the writer (PIRT 2000) and has apparently not elsewhere appeared in the literature although Smorodinski (1962 etc.) used related formulae from which it could easily have been deduced. The symmetrical formulae (14), (15) were used in the physics literature from 1962. See Wick (1962), Smorodinski (1963) etc. On the derivation see Hestenes *Space-time Algebra* 1966

5. Hyperbolic Velocity

Instead of the nondimensional rapidity w it is more natural in physical applications to use the corresponding dimensional quantity

$$V = c\,w = c\,\mathrm{th}^{[-1]}(v/c) \qquad (1)$$

This was used by Varićak who regarded it as the true velocity from which the usual velocity v is found as a Euclidean projection. This is here accepted as a correct view although for the sake of conforming with customary usage as regards the word 'velocity' the term *hyperbolic velocity* will be used to denote velocity as defined by equation (1). Since v and V have the same physical dimensions the relation between them can be shown as below where the scales of v and V are the same.

Fig: The relation between velocity and hyperbolic velocity.

* *Properties of hyperbolic velocity*

(a) Like rapidity, it can take any value from $-\infty$ to $+\infty$, the hyperbolic velocity of light being infinite. When $v \to c$ correspondingly $V \to \infty$
(b) At low velocities ($v \ll c$) hyperbolic velocity V approximates v or more precisely,

$$V = v\{\,1 + 1/3\,(v/c)^2 + 1/5\,(v/c)^4 + \ldots\,\} \qquad (2)$$

For rectilinear motion, hyperbolic velocities combine by the same rules of addition as do the proportional rapidities. So if the composition of velocities v_1 and v_2 gives velocity v then corresponding hyperbolic velocities are added:

$$V = V_1 + V_2 \tag{3}$$

* *The space of hyperbolic velocities*: Hyperbolic velocity vectors **V** are defined by their magnitude V and direction. The space of such vectors forms a hyperbolic space of radius of curvature c and defines the kinematic space in Special Relativity. This provides the constant c with a natural meaning and leads to a very satisfactory view of the principle of relativity which was well expressed by Borel (1913)

> *'The principle of relativity corresponds to the hypothesis that the kinematic space is a space of constant negative curvature, the space of Lobachevski and Bolyai The value of the radius of curvature is the speed of light.'*

The kinematic space approximates the classical velocity space locally for velocities small compared with the speed of light.

The addition of hyperbolic velocities comes from rewriting the formula for the combination of rapidities. The cosine rule giving the magnitude V for the combination of V_1 and V_2 inclined at angle θ becomes

$$\text{ch } V/c = \text{ch } V_1/c \text{ ch } V_2/c + \text{sh } V_1/c \text{ sh } V_2/c \cos\theta \tag{4}$$

Use of V instead of rapidity w simplifies diagrams, e.g.the Sommerfeld diagram in hyperbolic space becomes a figure such as that shown below

Note:
The addition law assumed in the present book follows the original idea of Varićak (1912). Addition of vectors in hyperbolic space by the method of parallel transport involves a rotational effect (See e.g. Richtermeyer: *Hyperbolic Geometry*, Springer 1992). This is due to the curvature of the space and occurs in relativity as the Thomson rotation. It leads to a result similar to the gyrovector as defined by Ungar except that it applies to hyperbolic vectors and not Cartesian vectors as does the gyrovector.

CHAPTER 9 – Differential Minkowski Space and Light Propagation

1. Differential Minkowski Space

The use of the differential form of the Lorentz transformation leads naturally to the concept of the differential Minkowski space of four-vectors (dt, dx, dy, dz) where all the ideas of normal Minkowski space apply to these differential vectors. Thus differential vectors are classified as time-like or space-like according to whether or not they lie in the differential Monge cone

$$c^2dt^2 = dx^2+dy^2+dz^2 \tag{1}$$

Only time-like vectors have significance for physical motion because the requirement

$$(dx/dt)^2 + (dy/dt)^2 + (dz/dt)^2 < c^2 \tag{2}$$

that the velocity should not exceed c, implies that

$$dx^2+dy^2+dz^2 < c^2dt^2 \tag{3}$$

So the differential vector (dt, dx, dy, dz) lies within the Monge cone. Usually it is the forward light-cone which is of most interest characterized by this last condition with $dt > 0$.

The Monge cone and the system of associated hyperbolic surfaces remain invariant relative to differential changes brought about by any homogeneous Lorentz transformation.

$$(cdt', dx', dy', dz') = L\,(cdt, dx, dy, dz) \tag{4}$$

The use of the differential form here allows the variables t', x', y', z' to be related to t, x, y, z by nonhomogeneous as well as homogeneous Lorentz transformations. This possibility is exactly in accord with Minkowski's original 1908 concept of the 'absolute world' as consisting of world vectors (t, x, y, z) invariant under the group of non-homogeneous Lorentz transformations. However the form of space he defined, i.e. the usual Minkowski space, is only invariant for homogeneous transformations corresponding to the chosen fixed origin. Differential Minkowski space gives more flexiblity permitting invariance also with respect to translations. It is consequently more in accord with Minkowski's conception of the absolute world.

2. The Cayley-Klein Metric in Differential Minkowski Space

In his *Theory of Relativity* which first appeared in 1921, Pauli briefly observed that Varićak's results could be derived from the Cayley-Klein theory of projective geometry but neither he nor others followed up this idea which will be described here in further detail

The space of differential vectors written in either of the two forms

$$(dt, dx, dy, dz), (c\,dt, dx, dy, dz) \tag{1}$$

gives rise to a projective space with the differential Monge cone

$$c^2\,dt^2 - dx^2 - dy^2 - dz^2 = 0 \tag{2}$$

as absolute. Since this locus is a real conic, the resulting projective space is hyperbolic. Vectors in this space lie within the Monge cone representing physically feasible motions satisfying the condition

$$dx^2 + dy^2 + dz^2 < c^2\,d\,t^2 \tag{3}$$

The Cayley-Klein projective distance between two differential vectors having suffices 1, 2 is

$$\mathrm{ch}^{[-1]}\,\frac{(c^2\,dt_1\,dt_2 - dx_1\,dx_2 - dy_1\,dy_2 - dz_1\,dz_2)}{\sqrt{(c^2\,dt_1^2 - dx_1^2 - dy_1^2 - dz_1^2)}\,\sqrt{(c^2\,dt_2^2 - dx_2^2 - dy_2^2 - dz_2^2)}}. \tag{4}$$

which is more conveniently written using vectors for the space part as

$$\mathrm{ch}^{[-1]}\,\frac{c^2\,dt_1\,dt_2 - d\mathbf{r}_1.d\mathbf{r}_2}{\sqrt{(c^2dt_1^{\,2} - d\mathbf{r}_1.d\mathbf{r}_1)}\,\sqrt{(c^2dt_2^{\,2} - d\mathbf{r}_2.d\mathbf{r}_2)}}. \tag{5}$$

On dividing through by $dt_1\,dt_2$ and denoting velocities $d\mathbf{r}/\,dt$ by $\mathbf{v}$ and we see that the distance so defined is just the relative rapidity w of the two velocities $\mathbf{v}_1$, $\mathbf{v}_2$ given by

$$\mathrm{ch}\,w = \frac{c^2 - \mathbf{v}_1.\mathbf{v}_2}{\sqrt{(c^2 - \mathbf{v}_1.\mathbf{v}_1)}\,\sqrt{(c^2 - \mathbf{v}_2.\mathbf{v}_2)}}. \tag{6}$$

so identifying the hyperbolic space as the Beltrami space of these velocity vectors.

In this space the Beltrami parametric representation

$$\begin{aligned} dx/dt &= v_x = c\,\mathrm{th}\,w\;n_1 = c\,\mathrm{th}\,w\;\sin\varphi\cos\theta \\ dy/dt &= v_y = c\,\mathrm{th}\,w\;n_2 = c\,\mathrm{th}\,w\;\sin\varphi\sin\theta \\ dz/dt &= v_z = c\,\mathrm{th}\,w\;n_3 = c\,\mathrm{th}\,w\;\cos\varphi \end{aligned} \tag{7}$$

can be viewed in a corresponding homogeneous form arising from

$$(c\,dt, dx, dy, dz) = \text{const.}\ (\text{ch}\,w, \text{sh}\,w\,n_1, \text{sh}\,w\,n_2, \text{sh}\,w\,n_3) \tag{8}$$

It implies

$$c^2\,dt^2 - dx^2 - dy^2 - dz^2 = (\text{const})^2 \tag{9}$$

identifying the constant multiplier as $c\,d\tau$. Thus

$$\begin{aligned} c\,dt &= c\,d\tau\ \text{ch}\,w &&= c\,d\tau\ \text{ch}\,w \\ dx &= c\,d\tau\ \text{sh}\,w\ n_1 &&= c\,d\tau\ \text{sh}\,w \sin\varphi \cos\theta \\ dy &= c\,d\tau\ \text{sh}\,w\ n_2 &&= c\,d\tau\ \text{sh}\,w \sin\varphi \sin\theta \\ dz &= c\,d\tau\ \text{sh}\,w\ n_3 &&= c\,d\tau\ \text{sh}\,w \cos\varphi \end{aligned} \tag{10}$$

The parametrization (10) may also be written as giving the components of the Minkowski four-velocity

$$\begin{aligned} V_0 &= c\,dt/d\tau = c\,\text{ch}\,w &&= c\,\text{ch}\,w \\ V_1 &= dx/d\tau = c\,\text{sh}\,w\,n_1 &&= c\,\text{sh}\,w \sin\varphi \cos\theta \\ V_2 &= dy/d\tau = c\,\text{sh}\,w\ n_2 &&= c\,\text{sh}\,w \sin\varphi \sin\theta \\ V_3 &= dz/d\tau = c\,\text{sh}\,w\ n_3 &&= c\,\text{sh}\,w \cos\varphi \end{aligned} \tag{11}$$

Note that the space-time four-dimensionality arises from the use of homogeneous coordinates for three-dimensional motion.

* *Historical comment:* In view of its importance for the history of the present subject the remarks of Pauli are here quoted in full. In a footnote (*The Principle of Relativity*, p.74 in Engl. trans.) he says:

> *" Varićak establishes a formal connexion between the Lorentz transformation, as well as the relativistic formulae for the Doppler effect, aberration of light, and reflection in a moving mirror, with the Bolyai-Lobachevski geometry … This connexion with the Bolyai-Lobachevski geometry can be briefly described in the following way (this had not been noticed by Varićak): if one interprets dx_1, dx_2, dx_3, dx_4 as homogeneous coordinates in a three dimensional projective space, then the invariance of the equation $dx_1^2+dx_2^2+dx_3^2 - dx_4^2 = 0$ amounts to introducing a Cayley system of measurement based on a real conic section. The rest follows from the well known arguments of Klein (Math.Ann. 4 1871 12)"*

Pauli only allows a 'formal connexion' and not a 'real connexion'! As regards the reference to Klein, it is remarkable that Klein himself, the authority on both projective non-Euclidean geometry and relativity, had managed to miss the precise relation between the two, even in his 1910 paper: 'Über die geometrische Grundlagen der Lorentz-gruppe' devoted to exactly this question. The explanantion appears to be that, as shown both in Klein's paper and in Pauli's comment above, at that time it was customary to think in terms of the pseudo-Euclidean space-like metric which does not lend itself to the Cayley metric. The only place where the writer has found Klein using the appropriate time-like form is in a footnote of his book *Die Entwicklung* …. (p.131, vol.II) where he quoted the formula for Cayley-Klein distance for special relativity though using the Minkowski imaginary angle The reversed Cauchy inequality, the justification for this formula, was not mentioned.

3. The Light Cone Condition and Coordinate Invariance.

Suppose that a transformation of frames of reference is made resulting in the relation

$$[c\,dt', dx', dy', dz']^T = \Lambda\,[c\,dt, dx, dy, dz]^T \qquad (1)$$

Λ being a general Lorentz transformation. From this follows

$$c^2\,dt'^2 - dx'^2 - dy'^2 - dz'^2 = (c^2\,dt^2 - dx^2 - dy^2 - dz^2) \qquad (2)$$

So the Monge cones in the original and transformed spaces and their interiors correspond to each other (causality condition). More generally the same conclusion follows if there is a relation of the the type

$$c^2\,dt'^2 - dx'^2 - dy'^2 - dz'^2 = \kappa^2\,(c^2\,dt^2 - dx^2 - dy^2 - dz^2) \qquad (3)$$

where κ is any non-zero scalar multiplier. Such a relation may come about from the scalar multiplied form of the Lorentz transformation (e.g. the Voigt transformation) or from a nonlinear transformation of coordinates and time. Condition (3), fundamental to the theory; will be referred to as the *light-cone condition*. The following simple fact is basic.

PROPOSITION: The light-cone condition implies absolute invariance of the Cayley-Klein metric.

Proof: Any linear combination of two time-like differential vectors:

$$(c\,dt, dx, dy, dz) = \lambda\,(c\,dt_1, dx_1, dy_1, dz_1) + \mu\,(c\,dt_2, dx_2, dy_2, dz_2) \qquad (4)$$

with $\lambda, \mu > 0$ lies on the segment joining the two points with suffices 1 and 2 and so from the convexity of the Monge cone is also time-like. Under linear transformation of differentials it transforms to the vector

$$(c\,dt', dx', dy', dz') = \lambda\,(c\,dt'_1, dx'_1, dy'_1, dz'_1) + \mu\,(c\,dt'_2, dx'_2, dy'_2, dz'_2) \qquad (5)$$

This similarly lies within the Monge cone in the transform space and is time-like. Applying the light-cone condition equating coefficients of λ^2, $\lambda\mu$ and μ^2 we get

$$\begin{aligned}
c^2\,dt'^2_1 - dx'^2_1 - dy'^2_1 - dz'^2_1 &= \kappa^2\,(c^2\,dt_1^2 - dx_1^2 - dy_1^2 - dz_1^2)\\
c^2\,dt'_1 dt'_2 - dx'_1 dx'_2 - dy'_1 dy'_2 - dz'_1\,dz'_2 &= \kappa^2\,(c^2\,dt_1\,dt_2 - dx_1\,dx_2 - dy_1\,dy_2 - dz_1\,dz_2)\\
c^2\,dt'^2_2 - dx'^2_2 - dy'^2_2 - dz'^2_2 &= \kappa^2\,(c^2\,dt_2^2 - dx_2^2 - dy_2^2 - dz_2^2)
\end{aligned} \qquad (6)$$

From which follow invariance of the ratio giving Cayley-Klein metric and rapidity. The hyperbolic spaces in the original and transformed light-cones are correspondingly mapped on to one another isometrically. Rapidity and hyperbolic velocity are seen to be independent of the coordinate system under any differentiable coordinate transformation. Rapidity is an absolute invariant of the transformation and defines the hyperbolic geometry in Beltrami representation as described previously.

4. Normal Light Propagation

In 1924 Carathéodory published a general derivation of the light cone condition starting from an initial set of axioms relating to light propagation. The background to the paper is that in 1908, 1910 Bateman and Cunningham had discovered that the equation of the wave surface as also Maxwell's equations were invariant under certain nonlinear transformations related to inversion which they called 'spherical wave transformations'. The papers of Cunningham and Bateman thus raised the question of the exact nature of the group of transformations under which Maxwell's equations remain invariant and the relation of this group with Special Relativity. This problem, ascribed to Pauli by Carathéodory, was investigated in the paper.

Out of the initial axiomatic discussion Carathéodory established the existence of differentiable equations relating two systems of locally Euclidean coordinates and time of the form:

$$x' = X(x,y,z,t),\ y' = Y(x,y,z,t),\ z' = Z(x,y,z,t),\ t' = T(x,y,z,t) \qquad (1)$$

From these follow linear relations between corresponding differentials

$$[\, dx', dy', dz', dt' \,]^T = [\, J \,]\, [dx, dy, dz, dt\,]^T \qquad (2)$$

[J] is the Jacobian matrix. Using these linear relations we may express as a quadratic in terms of dx, dy, dz, dt the quantity

$$dx'^2 + dy'^2 + dz'^2 - c^2\, dt'^2 \qquad (3)$$

For normal light propagation to be preserved by the transformation there must be satisfied a condition:

$$dx'^2 + dy'^2 + dz'^2 - c^2\, dt'^2 = \mu\,(x, y, z, t)\,(dx^2 + dy^2 + dz^2 - c^2\, dt^2) \qquad (4)$$

- a similar condition to that previous found by Bateman in connexion with Maxwell's equations. It resembles the previous light cone condition but the multiplier μ (which should be positive) is a function of position and time instead of v. The condition is fundamental to Carathéodory's theory.

* *Huyghens wavelets:* The condition (4) can be given a physical interpretation for it implies that the infinitesimal spherical wave (a Huyghens wavelet)

$$dx^2 + dy^2 + dz^2 = c^2\, dt^2 \qquad (5)$$

transforms into a similar wavelet. These wavelets generate the wavefront which propagates according to equation of the wave-equation

$$(\partial V/\partial x)^2 + (\partial V/\partial y)^2 + (\partial V/\partial z)^2 - 1/c^2\,(\partial V/\partial t)^2 = 0 \qquad (6)$$

The light cone condition implies that this equation is also invariant under the transformation considered. This is because the dual equation of the Monge cone, giving the condition that a hyperplane with homogeneous coordinates (n_0, n_1, n_2, n_3) is tangential to the cone, is

$$n_1^2 + n_2^2 + n_3^2 - (n_0/c)^2 = 0 \qquad (7)$$

So the wave equation for V represents the condition that the vector

$$[\partial V/\partial x, \partial V/\partial y, \partial V/\partial z, \partial V/\partial t] \qquad (8)$$

is tangential to the Monge cone. On transforming to new coordinates, there will be a condition dual to the light-cone condition:

$$(n_1'^2 + n_2'^2 + n_3'^2 - (n_0'/c)^2) = \mu(x, y, z, t)^{-1} (n_1^2 + n_2^2 + n_3^2 - (n_0/c)^2) \qquad (9)$$

From this it immediately follows that the wave equation is satisfied in the new coordinates.

Carathéodory proved the invariance of the wavefront equation using the theory of characteristics for a partial differential equation and showed that any piecewise linear light path becomes transformed into another piecewise linear light path.

References: See Carathéodory: 'On the axiomatics of special relativity …' (German) Preuss. Akad Wiss. 1923 reproduced in his collected works. There is also a shorter version in German in his collected works which is the translation of an encyclopedia article published in Greek. The papers of Bateman and Cunningham are listed in the bibliography.

5. Conformal Transformation in Four Dimensions

With $l = ict$, $l' = ict'$ the light-cone condition can be written as

$$dx'^2 + dy'^2 + dz'^2 + dl'^2 = \mu(x, y, z, t)(dx^2 + dy^2 + dz^2 + dl^2) \qquad (1)$$

This is the condition for a conformal transformation in 4 dimensions. One such conformal transformation is the Lorentz transformation. Another is the inversion:

$$\begin{aligned} x' &= x / (x^2+y^2+z^2+l^2) \\ y' &= y / (x^2+y^2+z^2+l^2) \\ z' &= z / (x^2+y^2+z^2+l^2) \\ l' &= 1 / (x^2+y^2+z^2+l^2) \end{aligned} \qquad (2)$$

When translated back to x, y, z, t variables this coincides with one of the spherical wave transformations of Bateman & Cunningham. The importance of inversion is seen from the following result:

THEOREM (Liouville 1847): Every conformal transformation in a space of more than 2 dimensions is representable by a sequence of similarity transformations and inversions.

The similarity transformations are those generated by orthogonal transformations and translations. A simplified proof of the theorem was given by Carathéodory in his 1923 paper.

Concerning the application of the spherical wave transformations to relativity, an important example is the following which arose in Bateman's 1910 paper

EXAMPLE Consider the infinitesimal transformation

$$
\begin{aligned}
t' &= t\,(1 + f\,x) \\
x' &= x\,(1 + f\,x) + \tfrac{1}{2} f\,(-x^2 + c^2t^2 - y^2 - z^2) \\
y' &= y\,(1 + f\,x) \\
z' &= z\,(1 + f\,x)
\end{aligned}
\tag{3}
$$

f is here considered small so that only terms of the first order in f need be retained. The conformal condition is satisfied with

$$\mu\,(x,y,z,t) = 1 + 2\,f\,x \tag{4}$$

On substituting for t from the first equation into the second we find

$$x' = x + \tfrac{1}{2} f\,(x^2 + t'^2 - y^2 - z^2) \tag{5}$$

With x, y, z fixed, the point with coordinate x' moves with constant acceleration f. As Bateman observed, the relation between t and t' agrees with that given by Einstein (1907) in his attempt to extend the Special Theory to an accelerated system.

This is an example of a non-Galilean transformation which nevertheless satisfies the condition of normal light propagation. Carathéodory considered that such transformations should be excluded from the invariance group of Special Relativity since he was understanding in his paper the principle of Special Relativity to include the principle of mechanical relativity, i.e. that all phenomena take place in an inertial frame. As a result the conclusion of Carathéodory is that the invariance group of Special Relativity is the non-homogeneous Lorentz group with scalar multiplication

However, since those nonlinear transformations obey the light cone condition, it follows from above that the Cayley-Klein metric defining an invariant rapidity can be introduced leading to the Beltrami interpretation together with its consequences e.g. all those which follow from the composition of velocities. The writer's opinion is that in view of this the status of the nonlinear transformations in the special theory must remain an open and important question.

Reference: For further comments see the writer's paper at the congress *'Constantin Carathéodory'* Orestiada, Greece, Sept. 2000.

APPENDIX 2 - Mathematical Notes

1. Spherical Trigonometry

A spherical triangle is formed by three great-circle arcs on the surface of a sphere. The vertices and the angles at these vertices are usually denoted by A, B, C and the lengths of the sides by a, b, c. The sides may alternatively be characterized by the angles α, β, γ they subtend at the centre of the sphere which are related to a, b, c by

$$\alpha = a/R,\ \beta = b/R,\ \gamma = c/R$$

R is here the radius. The principal formulae are then, relative to vertex A:

(a) *The cosine formulae*:

$$\cos\alpha = \cos\beta\cos\gamma + \sin\beta\sin\gamma\cos A \quad \text{etc.}$$
$$\cos a/R = \cos b/R\cos c/R + \sin b/R\sin c/R\cos A \quad \text{etc.}$$

(b) *The sine formula*:

$$\sin A/\sin\alpha = \sin B/\sin\beta = \sin C/\sin\gamma$$

(c) *The polar cosine formulae*: With any point on a sphere is associated the equatorial great circle having this point as a pole. An orientation of this great circle may be determined by the right handed corkscrew rule. Then the three vertices of any triangle have three associated great circles forming what is called the *polar triangle*. The relation between a triangle and its polar triangle is reciprocal. The angles α, β, γ, A, B, C of either triangle correspond to π-A, π-B, π-C, $\pi-\alpha$, $\pi-\beta$, $\pi-\gamma$ of the other. The cosine rule applied to the polar triangle gives polar cosine formulae

$$\cos A = -\cos B\cos C + \sin B\sin C\cos\alpha \quad \text{etc.}$$

* *Remark*: The sine rule may be deduced from the cosine formula by writing

$$\sin^2 A = 1 - \cos^2 A = \frac{(\sin\beta\sin\gamma)^2 - (\cos\alpha - \cos\beta\cos\gamma)^2}{(\sin\beta\sin\gamma)^2}$$

The denominator on the right which will be denoted by f^2 ($f > 0$) can be brought to a symmetrical form:

$$\begin{aligned}&(\sin\beta\sin\gamma)^2 - (\cos\alpha - \cos\beta\cos\gamma)^2\\ &\quad = (1-\cos^2\beta)(1-\cos^2\gamma) - \cos^2\alpha + 2\cos\alpha\cos\beta\cos\gamma - \cos^2\beta\cos^2\gamma\\ &\quad = 1 - \cos^2\alpha - \cos^2\beta - \cos^2\gamma + 2\cos\alpha\cos\beta\cos\gamma\end{aligned}$$

The sine rule then follows from the symmetry of formula.

$$\frac{\sin A}{\sin\alpha} = \frac{f}{\sin\alpha\sin\beta\sin\gamma},$$

Fig. A right-angled spherical triangle

* *Right-angled triangles*:

The formulae for a right angled triangle are the following (with B as right angle)

(a) *The cosine rule (Pythagoras' theorem)*

$$\cos\beta = \cos\alpha \ \cos\gamma$$

(b) *The sine rule*

$$\sin\alpha = \sin A \sin\beta$$
$$\sin\gamma = \sin C \sin\beta$$

(c) *The tangent rule*:

$$\tan\gamma = \cos A \tan\beta$$
$$\tan\alpha = \cos C \tan\beta$$

(d) *The adjacent side rule*

$$\tan\alpha = \tan A \sin\gamma$$
$$\tan\gamma = \tan C \sin\alpha$$

(e) *The cotangent rule*:

$$\cos\beta = \cot A \cot C$$

(f) *The adjacent angle rule*:

$$\cos A = \sin C \cos\alpha$$
$$\cos C = \sin A \cos\gamma$$

Some may be deduced geometrically by projecting the triangle on to a tangent plane as described in the text while others are simple deductions from these. These 10 formulae cover all possible combinations of the unknowns A, B, a, b, c. They may all be deduced diagramatically from *Napier's Rule*. For further details on these matters see Todhunter & Leathem's book.

---

* *Reference*: Todhunter & Leathem: *Spherical Trigonometry* London (1919). An excellent text written "for schools" The above formulae are as given in this book transcribed for the case when B is a right angle.

* *Spherical excess*: From the polar cosine formula may be deduced that the sum of the angles of a spherical triangle is greater than π.

$$\begin{aligned} \cos A &= -\cos B \cos C + \sin B \sin C \ \cos a/R \\ &< -\cos B \cos C + \sin B \sin C \\ &= -\cos (B+C) \\ &= \cos (\pi - B - C) \end{aligned}$$

from which

$$A < \pi - B - C, \text{ i.e. } A+B+C < \pi$$

The *spherical excess* is the positive difference

$$E = (A+B+C) - \pi$$

It gives the area of a spherical triangle by *Giraud's formula*

$$\text{area} = E R^2$$

* *Lagrange's formula for excess*: numerous formulae have been given for finding the excess. The most appropriate for this book is that described by Lagrange (1799) which is

$$\cot (E/2) = \frac{\cos \beta/2 \cos \gamma/2 + \sin \beta/2 \sin \gamma/2 \cos A}{\sin \beta/2 \sin \gamma/2 \sin A} = \frac{\cot \beta/2 \cot \gamma/2 + \cos A}{\sin A}$$

Lagrange's derivation was the following

$$\cot (E/2) = -\tan (A + B + C)/2 = -\frac{\tan A/2 + \tan (B + C)}{1 - \tan A/2 \ \tan (B + C)/2}$$

Now use is made of the identity

$$\frac{\tan (B + C)/2}{\cot A/2} = \frac{\cos (\beta - \gamma)/2}{\cos (\beta + \gamma)/2}$$

which is one of 'Napier's analogies' (SeeTodhunter & Leathem) Substituting for tan (B + C)/2, leads to the required expression

$$\cot (E/2) = -\frac{\tan A/2 \cos (\beta + \gamma)/2 + \cot A/2 \cos (\beta - \gamma)/2}{\sin \beta/2 \sin \gamma/2 \sin A}$$

$$= \frac{\cos \beta/2 \cos \gamma/2 + \sin \beta/2 \sin \gamma/2 \cos A}{\sin \beta/2 \sin \gamma/2 \sin A}$$

Lagrange showed that this may be converted to a symmetric form as shown in the analogous hyperbolic case below.

Reference: Lagrange's paper: 'Solution de quelques problèmes ...' may be read in his Collected Works: *Oeuvres* VII 331-359 (see especially 339)

2. Hyperbolic Trigonometry

We pass from the formulae for a sphere of constant Gaussian curvature R^2 to corresponding formulae for a two-dimensional hyperbolic space of constant Gaussian curvature $-R^2$ by changing R into iR (Taurinus' theorem). This is equivalent to changing angles from α, β, γ to $\alpha/i, \beta/i, \gamma/i$ i.e. to $-i\alpha, -i\beta, -i\gamma$. Then reinterpreting sine, cosine of imaginary angles as sinh, cosh (abbreviated sh, ch) there are found the corresponding hyperbolic formulae:

(a) *The hyperbolic cosine formula*:

$$\mathrm{ch}\,\alpha = \mathrm{ch}\,\beta\,\mathrm{ch}\,\gamma - \mathrm{sh}\,\beta\,\mathrm{sh}\,\gamma\cos A \quad \text{etc.}$$
$$\mathrm{ch}(a/R) = \mathrm{ch}(b/R)\,\mathrm{ch}(c/R) - \mathrm{sh}(b/R).\mathrm{sh}(c/R).\cos A \quad \text{etc.}$$

(b) *The hyperbolic sine formulae*:

$$\sin A/\,\mathrm{sh}\,\alpha = \sin B/\,\mathrm{sh}\,\beta = \sin C/\,\mathrm{sh}\,\gamma$$

(c) *The hyperbolic polar cosine formula*:

$$\cos A = -\cos B\cos C + \sin B\sin C\,\mathrm{ch}\,\alpha \quad \text{etc.}$$

* *Remark*: The hyperbolic sine rule may be deduced in the same way as in the spherical case from the hyperbolic cosine formula by writing

$$\sin^2 A = 1 - \cos^2 A = 1 - \frac{(\mathrm{ch}\,\beta\,\mathrm{ch}\,\gamma - \mathrm{ch}\,\alpha)^2}{(\mathrm{sh}\,\beta\,\mathrm{sh}\,\gamma)^2}$$

From this the sine rule follows from the symmetrical right hand side of

$$\frac{\sin A}{\mathrm{sh}\,\alpha} = \frac{\sqrt{(1 - \mathrm{ch}^2\alpha - \mathrm{ch}^2\beta - \mathrm{ch}^2\gamma + 2\,\mathrm{ch}\,\alpha\,\mathrm{ch}\,\beta\,\mathrm{ch}\,\gamma)}}{\mathrm{sh}\,\alpha\,\mathrm{sh}\,\beta\,\mathrm{sh}\,\gamma}$$

* *Infinite triangles*: In hyperbolic geometry it is possible to have infinite triangles with one or more of the vertex angles zero. One such triangle is shown below formed by the perpendicular and an asymptotic parallel to a straight line BA from a point C not on this line.

Fig: The parallel angle Π(a) of Lobachevsky

The angle B is the parallel angle of Lobachevsky denoted by him by $\Pi(a)$ showing its dependence on the length a of the perpendicular CB. The right-angled triangle ABC has one zero angle and two infinite sides. On putting $A = 0$, $B = \Pi(a)$, $C = \pi/2$, $b = \infty$, $c = \infty$ in the above polar cosine formula for cos A follows,

$$1 = \sin \Pi(a) \operatorname{ch} \alpha$$

From this follows the formulae of Lobachevsky for the parallel angle:

$$\sin \Pi(a) = 1/\operatorname{ch}(a/R)$$
$$\cos \Pi(a) = \operatorname{th}(a/R)$$
$$\tan \Pi(a) = 1/\operatorname{sh}(a/R)$$

* *References on hyperbolic geometry*: The literature is considerable. Standard texts are those of Bonola, Sommerville while the books of Coxeter, Rosenfeld and Shirokov are to be recommended. Bonola includes a translation of Bolyai's work. Not much of the original work of Lobachevski is easily available in translation Apart from a small introductory volume originally published in German, there is available one article in French, 'Géometrie imaginaire' and an English translation of a later work 'Pangeometry' both listed at the end of this appendix.

* *Right-angled hyperbolic triangles*:

With B as right angle the formulae corresponding to the spherical case are as follows

(a) *The hyperbolic cosine rule*

$$\operatorname{ch} \beta = \operatorname{ch} \alpha \operatorname{ch} \gamma$$

(b) *The hyperbolic sine rule*

$$\operatorname{sh} \alpha = \sin A \operatorname{sh} \beta$$
$$\operatorname{sh} \gamma = \sin C \operatorname{sh} \beta$$

(c) *The hyperbolic tangent rule*:

$$\operatorname{th} \gamma = \cos A \operatorname{th} \beta$$
$$\operatorname{th} \alpha = \cos C \operatorname{th} \beta$$

(d) *The hyperbolic adjacent side rule*

$$\operatorname{th} \alpha = \tan A \operatorname{sh} \gamma$$
$$\operatorname{th} \gamma = \tan C \operatorname{sh} \alpha$$

(e) *The hyperbolic cotangent rule*

$$\operatorname{ch} \beta = \cot A \cot C$$

(f) *The hyperbolic adjacent angle rule*

$$\cos A = \sin C \operatorname{ch} \alpha$$
$$\cos C = \sin A \operatorname{ch} \gamma$$

As with spherical formulae, these 10 formulae cover all possible combinations of the unknowns A, B, a, b, c and may be set out by a modified form of Napier's Rule. Certain of these formulae may be deduced by projection on to a tangential Euclidean plane (*the limiting plane*) as in the spherical case.

References:
1) For the hyperbolic Napier Rule, due to Engel, see Sommerville: *Non-Euclidean Geometry*
2) The method of projection on to the limiting plane is described in Shirokov: *A sketch of the fundamentals of Lobachevskian geometry*, (1964)

* *Hyperbolic defect*: From the polar cosine formula it may be shown that the sum of the angles of a hyperbolic triangle is less than π. Following a similar method to the spherical case we have

$$\begin{aligned} \cos A &= -\cos B \cos C + \sin B \sin C \ \mathrm{ch}\, a/R \\ &> -\cos B \cos C + \sin B \sin C \\ &= -\cos (B+C) \\ &= \cos (\pi - B - C) \end{aligned}$$

From which follows

$$A < \pi - B - C \quad \text{i.e. } A+B+C < \pi$$

The *hyperbolic defect* is defined as the positive difference

$$D = \pi - (A+B+C)$$

It gives the area of a hyperbolic triangle by a formula due to Gauss (cf the spherical case)

$$\text{area} = D R^2$$

* *The Hyperbolic Form of Lagrange's Formula for Excess (Area)*:

Lagrange's formula becomes

$$\cot (D/2) = \frac{\mathrm{ch}\, \beta/2 \ \mathrm{ch}\, \gamma/2 + \mathrm{sh}\, \beta/2 \ \mathrm{sh}\, \gamma/2 \cos A}{\mathrm{sh}\, \beta/2 \ \mathrm{sh}\, \gamma/2 \sin A}$$

LEMMA: In any hyperbolic triangle,

$$\frac{\tan (B + C)}{2} = \frac{\mathrm{ch}\, (\beta-\gamma)/2}{\mathrm{ch}\, (\beta+\gamma)/2} \cot \frac{A}{2}$$

This is the first of Napier's analogies for a hyperbolic triangle. Its proof is similar to the spherical case. From it the Lagrange formula follows easily:

$$\cot (D/2) = \tan (A+B+C)/2 = \frac{\tan A/2 + \tan(B+C)/2}{1 + \tan A/2 \tan(B+C)/2}$$

By the lemma the right hand side is

$$\begin{aligned} \text{rhs} &= \frac{\tan(A/2)\, \mathrm{ch}(\beta+\gamma)/2 - \cot(A/2)\, \mathrm{ch}(\beta-\gamma)/2}{\mathrm{ch}(\beta+\gamma)/2 - \mathrm{ch}\, (\beta-\gamma)/2} \\ &= \frac{\mathrm{ch}\, \beta/2 \ \mathrm{ch}\, \gamma/2 + \mathrm{sh}\, \beta/2 \ \mathrm{sh}\, \gamma/2 \cos A}{\mathrm{sh}\, \beta/2 \ \mathrm{sh}\, \gamma/2 \sin A} \end{aligned}$$

Reference: See Sommerville (1914) for Gauss' simple proof of his formula for area of a hyperbolic triangle.

* *The symmetric form of the Lagrange formula*: The formula may be further transformed by multiplying both denominator and numerator by 4 ch β/2 ch γ/2:

$$\text{rhs} = \frac{4\,(\text{ch}\,\beta/2\ \text{ch}\,\gamma/2)^2 + 4\,\text{ch}\,\beta/2\ \text{ch}\,\gamma/2\ \text{sh}\,\beta/2\ \text{sh}\,\gamma/2\ \cos A}{4\,\text{ch}\,\beta/2\ \text{ch}\,\gamma/2\ \text{sh}\,\beta/2\ \text{sh}\,\gamma/2\ \sin A}$$

The numerator is then, converting to whole angles,

$$\begin{aligned}&(\text{ch}\,\beta + 1)(\text{ch}\,\gamma + 1) + \text{sh}\,\beta\ \text{sh}\,\gamma\ \cos A\\ &\quad = (\text{ch}\,\beta - 1)\,(\text{ch}\,\gamma - 1) + \text{ch}\,\alpha - \text{ch}\,\beta\ \text{ch}\,\gamma\\ &\quad = 1 + \text{ch}\,\alpha + \text{ch}\,\beta + \text{ch}\,\gamma\end{aligned}$$

while the denominator is, by the hyperbolic sine rule,

$$\text{sh}\,\beta\ \text{sh}\,\gamma\ \sin A = \sqrt{(1 - \text{ch}^2\alpha - \text{ch}^2\beta - \text{ch}^2\gamma + 2\,\text{ch}\,\alpha\ \text{ch}\,\beta\ \text{ch}\gamma)}$$

resulting in the symmetric formula

$$\cot (D/2) = \frac{1 + \text{ch}\,\alpha + \text{ch}\,\beta + \text{ch}\,\gamma}{\sqrt{(1 - \text{ch}^2\alpha - \text{ch}^2\beta - \text{ch}^2\gamma + 2\,\text{ch}\,\alpha\ \text{ch}\,\beta\ \text{ch}\,\gamma)}}.$$

Here cos (D/2) and sin (D/2) will be proportional to the numerator and denominator respectively. The constant of proportionality is easily identified by squaring and adding giving

$$\cos (D/2) = \frac{1 + \text{ch}\,\alpha + \text{ch}\,\beta + \text{ch}\,\gamma}{4\,(\text{ch}\,\alpha/2)(\text{ch}\,\beta/2)(\text{ch}\,\gamma/2)}$$

$$\sin (D/2) = \frac{\sqrt{(1 - \text{ch}^2\alpha - \text{ch}^2\beta - \text{ch}^2\gamma + 2\,\text{ch}\,\alpha\ \text{ch}\,\beta\ \text{ch}\,\gamma)}}{4\,(\text{ch}\,\alpha/2)(\text{ch}\,\beta/2)(\text{ch}\,\gamma/2)}$$

3. Cayley-Klein Projective Metric

Cayley (1869) showed how the concept of distance could be introduced into projective geometry relative to an absolute conic (or simply 'absolute') having equation

$$a(x, x) = 0$$

Here a(x, y) is a bilinear form in the vectors x, y of a projective space.

$$a(x, y) = \sum_{i,j=1} \sum a_{ij} x_i y_j$$

Projective distance ρ is defined relative to the absolute by the formula

$$\rho = \cos^{[-1]} \frac{a(x,y)}{\sqrt{\{a(x,x)\, a(y,y)\}}}.$$

In three dimensions setting

$$a(x, x) = x_1^2 + x_2^2 + x_3^2$$

makes the absolute an imaginary locus and the Cayley definition gives the angle between the vectors x and y or, if these lie on a sphere with centre at the origin, the arc length on the surface of the sphere.

Klein (1871) considerably developed Cayley's idea by a method based on cross-ratios leading to a unified treatment by projective geometry of Euclidean, spherical and Lobachevskian geometries according to the nature of the absolute conic. He introduced the terms parabolic, elliptic or hyperbolic respectively to denote the three basic geometries.

In the hyperbolic case the quadratic a(x, x) is semi-definite so the absolute becomes a real ellipse and in view of the reversed Cauchy inequality the Cayley formula must be written as

$$\rho = \mathrm{ch}^{[-1]} \frac{a(x,y)}{\sqrt{\{a(x,x)\, a(y,y)\}}}.$$

Ordinary Euclidean geometrical ideas apply in the interior of this ellipse but straight lines are considered to meet only if the meeting point lies in its interior. So lines do not necessarily meet and are then considered parallel. Lines meeting on the ellipse are defined as asymptotically parallel, the bounding conic thus representing infinity. With these conventions it is found that all Euclidean axioms are satisfied except those relating to parallels

* *Relation to the Riemannian form*: It is easy to show an equivalent formula for ρ is

$$\text{sh}\,\rho = \frac{\sqrt{[a(x,y)^2 - a(x,x).a(y,y)]}}{\sqrt{[a(x,x)\,a(y,y)]}}$$

On putting y = x + dx there is found for the infinitesimal metric element squared:

$$ds^2 = \frac{a(x,dx)^2 - a(x,x)\,a(dx,dx)}{a(x,x)^2} = \frac{a(x,dx)^2}{a(x,x)^2} - \frac{a(dx,dx)}{a(x,x)}$$

It relates Cayley-Klein and Riemannian metrics. This formula shows that tangential elements to the surface a(x, x) = const (> 0) satisfying the constraint that a(x,dx) = 0 have metric element squared

$$ds^2 = -\,a(dx, dx)/\text{ const.}$$

Note the unexpected minus sign.

* *References*: The original reference to Cayley's work is the last part of his 'Sixth Memoir on Quantics': *Phil. Trans.* 1859. Kleins' work was published in his elegantly written: *Nicht Euklidische Geometrie* reprinted by Chelsea 1927. See also Veblen & Young': *Projective Geometry* (Ginn) for a fine exposition.

4 The Beltrami-Klein Representation:

Plane hyperbolic geometry is represented by the geometry of line segments within a circle as in fig.1. Two line segments are considered to be asymptotically parallel if they meet on the circle as in fig.2.

Fig.1 Intersecting and non-intersecting lines.

*Fig.*2: Asymptotic parallels

* *The Cayley-Klein metric*: If the equation is centred at the origin and has radius R, its equation is

$$x^2 + y^2 = R^2$$

which may be put into homogeneous form by writing X/Z, Y/Z for x and y so that

$$X^2 + Y^2 - R^2 Z^2 = 0$$

With this as absolute, the Cayley-Klein distance ρ is,

$$\operatorname{ch}\frac{\rho}{R} = \frac{(R^2 Z_1 Z_2 - X_1 X_2 - Y_1 Y_2)}{\sqrt{\{(R^2 Z_1^2 - X_1^2 - Y_1^2)(R^2 Z_2^2 - X_2^2 - Y_2^2)\}}},$$

This in nonhomogeneous form is

$$\operatorname{ch}\frac{\rho}{R} = \frac{(R^2 - x_1 x_2 - y_1 y_2)}{\sqrt{[(R^2 - x_1^2 - y_1^2)(R^2 - x_2^2 - y_2^2)]}}.$$

From the last equation is found

$$\operatorname{sh}\frac{\rho}{R} = \frac{R\sqrt{[(x_1 - x_2)^2 + (y_1 - y_2)^2 - (x_1 y_2 - x_2 y_1)]}}{\sqrt{(R^2 - x_1^2 - y_1^2)(R^2 - x_2^2 - y_2^2)\}}}$$

$$\operatorname{th}\frac{\rho}{R} = \frac{R\sqrt{[(x_1 - x_2)^2 + (y_1 - y_2)^2 - (x_1 y_2 - x_2 y_1)]}}{(R^2 - x_1 x_2 - y_1 y_2)}$$

* *Polar formulae*: Using the formula for th (ρ/R), the distance ρ from the origin (0,0) to a general point (x,y) at radial distance r is found from

$$\operatorname{th}\frac{\rho}{R} = \frac{r}{R}$$

giving the parametric Beltrami form for the nonhomogeneous case as

$$x = r\cos\theta = R\operatorname{th}(\rho/R)\cos\theta$$
$$y = r\sin\theta = R\operatorname{th}(\rho/R)\sin\theta$$

and for the homogeneous case,

$$X = R\operatorname{sh}(\rho/R)\cos\theta$$
$$Y = R\operatorname{sh}(\rho/R)\sin\theta$$
$$Z = \operatorname{ch}(\rho/R)$$

The coordinates X, Y, Z (usually termed *Weierstrass coordinates)*, satisfy identically

$$-X^2 - Y^2 + R^2 Z^2 = R^2$$

* *The Riemannian form*: The infinitesimal metric squared element (non-dimensional) is found from the formula for sh(ρ/R) or th (ρ/R) as

$$\frac{R^2\{(R^2-y^2)\,dx^2 + 2xy\,dxdy + (R^2-x^2)\,dy^2\}}{(R^2-x^2-y^2)^2}$$

$$\frac{R^2\{(R^2-x^2-y^2)\,dx^2 + (R^2-x^2-y^2)\,dy^2 + (xdy-ydx)^2\}}{(R^2-x^2-y^2)^2}$$

$$\frac{R^2(dx^2+dy^2)}{(R^2-x^2-y^2)} + \frac{(xdy-ydx)^2}{(R^2-x^2-y^2)^2}$$

Changing to polar coordinates gives the metric element squared as

$$\frac{dr^2}{1 - r^2/R^2} + \frac{r^2\, d\theta^2}{(1 - r^2/R^2)^2}$$

The further change to Beltrami coordinates gives it as

$$d\rho^2 + R^2\, sh^2(\rho/R)\, d\theta^2$$

* *The 3-dimensional case*: The region within the circle now becomes the region

$$x^2+y^2+z^2 < R^2$$

The radial distance from the origin (0, 0, 0) to point $\mathbf{r} = (x, y, z)$ is found as before as

$$th\,(\rho/R) = r/R$$

It gives the parametric form of the Beltrami representation in spherical coordinates:

$$\begin{aligned} x &= R\, th\,(\rho/R) \sin\varphi \cos\theta \\ y &= R\, th\,(\rho/R) \sin\varphi \sin\theta \\ z &= R\, th\,(\rho/R) \cos\varphi \end{aligned}$$

The corresponding homogeneous form using Weierstrass coordinates (X, Y, Z, T) is

$$\begin{aligned} T &= ch\,(\rho/R) \\ X &= R\, sh\,(\rho/R) \sin\varphi \cos\theta \\ Y &= R\, sh\,(\rho/R) \sin\varphi \sin\theta \\ Z &= R\, sh\,(\rho/R) \cos\varphi \end{aligned}$$

These parametrize the hyperboloid:

$$-X^2 - Y^2 - Z^2 + R^2 T^2 = R^2$$

* *The Cayley metric*: Using $\mathbf{r}$ to denote vectors (x, y, z), equivalent forms for the nonhomogeneous Cayley metric giving distance from $\mathbf{r}_1$ to $\mathbf{r}_2$ are

$$ch\,\rho = \frac{R^2 - \mathbf{r}_1.\mathbf{r}_2}{\sqrt{(R^2 - \mathbf{r}_1.\mathbf{r}_1)(R^2 - \mathbf{r}_2.\mathbf{r}_2)}}$$

$$sh\,\rho = \frac{\sqrt{[R^2\,(\mathbf{r}_2 - \mathbf{r}_1).(\mathbf{r}_2 - \mathbf{r}_1) - [(\mathbf{r}_1.\mathbf{r}_1)\,(\mathbf{r}_2.\mathbf{r}_2) - (\mathbf{r}_1.\mathbf{r}_2)^2]]}}{\sqrt{(R^2 - \mathbf{r}_1.\mathbf{r}_1)(R^2 - \mathbf{r}_2.\mathbf{r}_2)}}$$

$$= \frac{[R^2(\mathbf{r}_2 - \mathbf{r}_1).(\mathbf{r}_2 - \mathbf{r}_1) - (\mathbf{r}_1 \times \mathbf{r}_2).(\mathbf{r}_1 \times \mathbf{r}_2)]}{\sqrt{(R^2 - \mathbf{r}_1.\mathbf{r}_1)(R^2 - \mathbf{r}_2.\mathbf{r}_2)}}$$

The last step used the Lagrange identity

$$(\mathbf{r}_1.\mathbf{r}_1)(\mathbf{r}_2.\mathbf{r}_2) - (\mathbf{r}_1.\mathbf{r}_2)^2 = (\mathbf{r}_1 \times \mathbf{r}_2).(\mathbf{r}_1 \times \mathbf{r}_2)$$

The formula for th ρ may be found from these by division.

* *Riemannian metric*: Using the formula for sh ρ or th ρ and putting $\mathbf{r}_1 = \mathbf{r}$ and $\mathbf{r}_2 = \mathbf{r} + d\mathbf{r}$, we find for the nondimensional metric element squared:

$$\frac{R^2}{(R^2 - \mathbf{r}.\mathbf{r})^2} \{(R^2 - \mathbf{r}.\mathbf{r})(d\mathbf{r}.d\mathbf{r}) + (\mathbf{r}.d\mathbf{r})^2\}$$

Inside the bracket, using spherical coordinates,

$$\mathbf{r}.\mathbf{r} = r^2$$
$$d\mathbf{r}.d\mathbf{r} = (dr)^2 + r^2 (d\varphi^2 + \sin^2\varphi\, d\theta^2)$$
$$\mathbf{r}.d\mathbf{r} = xdx + ydy + zdz = \tfrac{1}{2}\, d(r^2) = r\, dr$$

and so

$$(R^2 - \mathbf{r}.\mathbf{r})(d\mathbf{r}.d\mathbf{r}) + (\mathbf{r}.d\mathbf{r}) = R^2 (dr)^2 + (R^2 - r^2)\, r^2 (d\varphi^2 + \sin^2\varphi\, d\theta^2)$$

Now substitution results in

$$\frac{R^2}{(R^2 - r^2)} \{dr^2 + r^2 (d\varphi^2 + \sin^2\varphi\, d\theta^2)\} + \frac{R^2}{(R^2 - r^2)^2} (r.dr)^2$$

$$= \frac{(dr/R)^2}{(1 - r^2/R^2)^2} + \frac{1}{(1 - r^2/R^2)} (r/R)^2 \{d\varphi^2 + \sin^2\varphi\, d\theta^2\}$$

The further transformation to Beltrami coordinates gives the dimensional metric element squared in the standard Riemannian form.

$$d\rho^2 + R^2 \operatorname{sh}^2(\rho/R)\, \{d\varphi^2 + \sin^2\varphi\, d\theta^2\}$$

---

* *Note*: Beltrami's original papers were published in the same year as the posthumously published dissertation of Riemann in 1868. They were the first to consider the application of Riemann's ideas to spaces of negative curvature. The Beltrami space was soon afterwards treated by an alternative projective approach by Klein (1871) and became better known under his name.

for the same two frames, where c is the speed of light, and $\gamma = (1 - V^2/c^2)^{-1/2}$. (a) Show that the Lorentz transformation reduces to the Galilean transformation for $V << c$, if x is also not too large. (b) Find the velocity transformation analogous to Eqs.3 using $v_x = dx/dt, v'_x = dx'/dt'$, etc. That is, observers at rest in the unprimed frame use time t to measure velocity, while observers at rest in the primed frame use t'. (c) Suppose something moves at the speed of light in the unprimed frame, with $(v_x, v_y, v_z) = (c, 0, 0)$. Find its velocity components in the primed frame moving at speed V in the x direction. Note that if one uses the Lorentz transformation, the velocity transformation is not performed by adding velocities vectorially.

Section 2.5 *Non-inertial frames*

2P23. At time $t = 0$, a ball is thrown sideways (i.e., perpendicular to the acceleration direction) by the crew member in the accelerating ship described in Section 2.5. What will be the shape $y(x)$ of its subsequent trajectory, as seen by the crew member? Here the coordinate x is along the acceleration direction, and y is the perpendicular coordinate, with $x = y = 0$ when the ball is thrown.

2P24. The position of a rocket as seen by observers in an inertial frame is $x = \alpha + \beta t + \gamma t^2$ as a function of time, where α, β,and γ are constants. In terms of any or all of these constants, find the rocket's (a) initial position x_0 (its position at time $t = 0$) (b) its initial velocity v_0 (c) its acceleration a. (d) Show that the velocity v of the rocket (at any time) obeys the relation $v^2 = v_0^2 + 2a(x - x_0)$.

2P25. During *Day One* the 12 m-radius Bubble rotated once every 2.0 minutes about an axis through its center. If an explorer pushes a ball from the Bubble center toward the rim at speed $v_b = 0.05$ m/s perpendicular to the axis of rotation, (a) how long does it take the ball to reach the rim? (b) Make a careful sketch of the ball's trajectory as seen by an observer rotating with the Bubble looking perpendicular to the plane of the ball's motion. How many times does the ball spiral around before reaching the rim?

2P26. During *Day One* the 12 m-radius Bubble rotated once every 2.0 minutes about an axis through its center. (a) Find the speed of the Bubble's rim as viewed from an inertial frame at rest relative to the rotation axis. (b) With what speed, and at what angle relative to a line from the rim to the Bubble's center, can a ball be thrown from the rim so that it passes through the Bubble's center and then returns to the thrower? Then sketch the ball's path in (c) the inertial frame (d) the rotating frame.

2P27. Suppose a Bubble frame rotates relative to an inertial frame, about their mutual z axes. The angle θ the x-axis of the rotating frame makes with the x-axis of the inertial frame is $\theta = 2\pi(t/T)$, as shown below, where t is the time and T is the period of rotation, the time to turn once around. (a) If (x, y, z) are the coordinates of a particle in the inertial frame, what are the coordinates (x', y', z') of the particle in the rotating frame of the Bubble, in terms of (x, y, z) and θ? (That is, find the coordinate transformation between an inertial and rotating frame analogous to the coordinate transformation Eqs. 1 between two inertial frames.) Then if $(x, y, z) = (1.0, 2.0, 3.0)$m, find (x', y', z') at times (b) $t = T/4$ (c) $t = T/2$, and draw a picture of the coordinates in each case to verify that your answers make sense.

Special Topic: *The Hubble expansion of the universe*

2P28. Hubble's law $v = H\ell$ relates the recessional velocities v of distant galaxies to their distances ℓ away from us at the present time. Here H is a constant of proportionality, the same for all galaxies. Suppose Hubble's constant $H = (657)$ (km/s)/Mpc. Here 1 Mpc = 10^6 parsecs, where 1 pc = 3.26 light-years; one light year is the distance light travels in 1.00 yr = 3.16×10^7 s, at speed $c = 3.00 \times 10^8$ m/s. If

15.2 Newton's law $F = ma$ in uniformly accelerating frames

How can we do physics in accelerating frames? How can we predict motion within an accelerating spaceship, in an elevator accelerating up or down, or in a car accelerating away from a stoplight? We need to have a law we can use to predict how things move.

Unfortunately, we already know that $\mathbf{F} = m\mathbf{a}$ *doesn't work* to observers in accelerating frames! For example, if we place a ball at rest in our accelerating spaceship and then take our hand away so that nothing touches the ball, then no forces act on it, so its acceleration should be zero. However, its acceleration from our point of view in the ship is *not* zero; the ball accelerates toward the floor. Newton's second law $\mathbf{F} = m\mathbf{a}$ is valid to observers in inertial frames, but not to those in accelerating frames.

Is there any way we can *rescue* $\mathbf{F} = m\mathbf{a}$? Can we find a way of "fixing it up" so it still works?

Consider the motion of a particle. We know that Newton's second law $\mathbf{F} = m\mathbf{a}$ governs the motion of a particle to observers in an *inertial* frame, where $\mathbf{F}$ is the total force acting on the particle. Multiplying Eq. 4 by the particle's mass m,

$$\begin{aligned} m\mathbf{a}' &= m\mathbf{a} - m\mathbf{a}_F \\ &= \mathbf{F} - m\mathbf{a}_F \,. \end{aligned} \tag{5}$$

This equation can be made to *look* like Newton's second law $m\mathbf{a}' = \mathbf{F}_{\text{Total}}$ if we define a new "pseudoforce"

$$\mathbf{F}_{\text{pseudo}} = -\, m\mathbf{a}_F \,, \tag{6}$$

opposite in direction to $\mathbf{a}_F$, that we have to add to the real forces. Then Newton's law

$$\mathbf{F}' \equiv \mathbf{F} + \mathbf{F}_{\text{pseudo}} = m\mathbf{a}' \tag{7}$$

is obeyed in the uniformly accelerating non-inertial frame *if we add this pseudoforce* $\mathbf{F}_{\text{pseudo}} = -\, m\mathbf{a}_F$ *to all the real forces when we find the total effective force* $\mathbf{F}'$ *in the accelerating frame.*

Now it is clear why there seems to be gravity within a uniformly accelerating spaceship. The ship has a constant acceleration $\mathbf{a}_F$, so the pseudoforce acts just like an effective gravity in the opposite direction, with $\mathbf{g}_{\text{eff}} = -\,\mathbf{a}_F$. This "effective gravitational force" is

$$\mathbf{F}_{\text{pseudo}} = -m\mathbf{a}_F = m\mathbf{g}_{\text{eff}}, \tag{8}$$

arising from the fact that on the ship we are observing motion from a non-inertial frame.

Sample Problem 3. A spaceship moving through gravity-free space has acceleration $\mathbf{a}_F$ in the y direction relative to inertial frames. The rest-frame of the ship is the primed frame. A ball is "dropped" from rest by a passenger on the ship, from a point a height y'_0 above the floor. Find the subsequent velocity v' and altitude y' of the ball as a function of time. Neglect air resistance.

Solution: No real forces act on the ball. However, in the accelerating (ship) frame, there is a pseudoforce $-m\mathbf{a}_F$, where m is the ball's mass and $\mathbf{a}_F$ is the acceleration of the ship as observed in an inertial frame. In the ship's frame Newton's law is $\mathbf{F}' = m\,\mathbf{a}'$, which in this case becomes simply $-m\mathbf{a}_F = m\,\mathbf{a}'$. The ball's acceleration relative to the ship is therefore $\mathbf{a}' = -\mathbf{a}_F$, a constant vector in the negative y' direction. Now $a' = dv'/dt$, so integrating $dv' = a'\,dt$ in the y' direction gives

$$v' = v'_0 + a'\,t = -\,a_F\,t$$

since $a' = -a_F$ is a constant and the ball starts with $v'_0 = 0$. Also $v' = dy'/dt$, so integrating once again gives

$$y' = y'_0 - (1/2)a_F t^2.$$

Working entirely in the accelerating frame, the pseudoforce behaves just like a real gravitational force. That is, if we define the magnitude of an *effective gravity* by $g_{\text{eff}} = a_F$, the above equations become $v' = -\,g_{\text{eff}}\,t$ and $y' = y'_0 - (1/2)g_{\text{eff}}\,t^2$, the usual equations for the velocity and altitude of a freely-falling particle in uniform gravity.

It is easy to understand the motion by viewing the ship and ball from the point of view of an inertial frame that was at rest relative to the ship at the instant the ball was dropped. According to observers in the inertial frame, the ball stays at rest while the "floor" of the spaceship accelerates up to meet it. It is obvious that shipboard passengers will see the ball "fall".

Sample Problem 4. Find the *weight* of a passenger of mass m standing in a spaceship whose acceleration is $\mathbf{a}_{\text{ship}}$ measured in an inertial frame.

Solution: The magnitude of the passenger's weight is the reading on the scale. *To an observer in the ship*, the scale and the passenger remain at rest. Two forces act on the passenger, the normal force N due to the scale (a *real* force) and the *pseudo*force $ma_F = mg_{\text{eff}}$, which behaves like an effective gravity acting toward the rear of the ship

The acceleration of the passenger is zero in this frame, so the two forces must sum to zero; that is,

$$F' = N - ma_F = ma' = 0,$$

so $N = ma_F$. By Newton's third law, if the force on the passenger due to the scale is N, the force of the observer on the scale is also N, in the opposite direction. Therefore the scale reads $N = ma_F$. The scale reading is the weight of the traveler, $W_{\text{traveler}} = ma_F$.

Alternatively, we can find the weight of the traveler by working in an *inertial* frame. To an observer in an inertial frame the ship, scale, and traveler all have the acceleration a_F upwards, as shown.

Only a single force acts on the traveler according to inertial observers: the normal force N of the scale, as shown. (In the inertial frame there is no pseudoforce behaving like an effective gravity; only real forces exist.) Therefore $F = ma$ gives

$$N = ma = ma_F.$$

The force on the scale due to the traveler is also N by the force-counterforce rule (Newton's third law), so the scale reads $N = ma_F$. This is the weight of the traveler, the same result we got by working in the accelerating frame of the ship.

15.3 Inertial and gravitational mass

Life inside our uniformly accelerating spaceship seems the same as life at rest on Earth or Iceworld. As long as we don't look outside to see ourselves rocketing through empty space rather than sitting at rest on the ground, we can't tell the difference. It feels like gravity when we walk around. A ball dropped in our accelerating ship "falls" as we see it, because to us there is a pseudoforce mg_{eff} acting downward, where g_{eff} has the magnitude of the ship's acceleration. If the ship were standing upright at rest on a planet, the ball would fall due to the *real* gravitational force mg.

Is there no way to tell whether the spaceship is at rest on the ground or accelerating uniformly in gravity-free space, assuming we don't look outside? There *is* a *potential* way to tell.

This potential way to tell involves a very interesting conceptual difference between two kinds of mass we can assign to every object. On the one hand, an object has the property of *inertial* mass m_{I}. Inertial mass represents the "sluggishness" of the object, the mass in ma. According to Newton's second law, the acceleration of the object is $a = F_{\text{net}}/m_{\text{I}}$, so that objects with a large inertial mass are harder to accelerate than objects with a small inertial mass. *Inertial mass is that intrinsic property of an object that resists acceleration.*

There is a quite different kind of mass. The *gravitational* mass m_{G} of an object is the mass in $F_{\text{grav}} = m_{\text{G}}g$, the gravitational force on the object when it is in a gravitational field g. If the mass m_{G} of one object is twice that of another object, gravity pulls on the first object twice as hard. *Gravitational mass is the intrinsic property of an object that is pulled upon by gravity.* Note that gravitational mass is conceptually quite different from inertial mass. There is no obvious reason why they should be the same.

Now we can see a potential way to tell whether we are living in a uniformly accelerating spaceship or are at rest on the ground, without peeking. Suppose first we drop a ball inside our accelerating ship. Then the pseudoforce $m_{\text{I}}\mathbf{g}_{\text{eff}} = -m_{\text{I}}\mathbf{a}_{\text{F}}$ acts downward on the ball. The mass in this case is the *inertial* mass m_{I}, because the pseudoforce actually originates on the ma side of Newton's law, as can be seen from Eqs. 5 and 6 where all the masses are inertial masses. Newton's law $\mathbf{F}' = m_{\text{I}}\mathbf{a}'$ applied to the ball in the accelerating ship then becomes $\mathbf{F}' = -m_{\text{I}}\mathbf{a}_{\text{F}} = m_{\text{I}}\mathbf{a}'$, so the acceleration $\mathbf{a}'$ of the ball relative to the ship is $\mathbf{a}' = -\mathbf{a}_{\text{F}}$. The masses cancel out, so any dropped ball accelerates downward relative to the ship with the same acceleration, whatever its inertial and gravitational masses may be.

But now suppose a ship is at rest on the ground, in uniform gravity g. If we dropped a ball in this ship, the real gravitational force $m_G g$ would act upon it. Newton's second law then becomes

$$F = m_G g = m_I a, \tag{11}$$

so the acceleration of the falling ball would be

$$a = \frac{m_G}{m_I} g. \tag{12}$$

Only if $m_G = m_I$ for all objects will everything fall with the same acceleration $a = g$.*

This provides a potential way to tell whether we are in our accelerating ship or are at rest on the ground. If for some object $m_G \neq m_I$, that object will fall differently in a ship at rest on the ground than it will in an accelerating spaceship. So we can figure out which kind of ship we are living in.

The experimental evidence obtained to date shows that the two kinds of mass are equal to one another, within experimental error.* If the equality is only *approximate*, or if there is some special substance with $m_G = 2\, m_I$, for example, then we could test whether real or artificial gravity were acting upon us. If a spaceship were at rest on the ground the special substance would fall twice as fast as anything else inside the ship. But if the ship were accelerating in empty space, the special substance would "fall" just like everything else, because m_G wouldn't make any difference in that case.

* More generally, we could allow the inertial masses of all objects to differ from their gravitational masses by a constant factor. That is, the ratio of m_G/m_I would have to be the same for all objects. If so, an accelerating frame could still be equivalent to a frame at rest in a gravitational field if the magnitude of the gravitational field g were adjusted appropriately.

Box 1. Newton's pendulums

Isaac Newton was well aware of the conceptual difference between the inertial and gravitational masses m_I and m_G, and sought to discover experimentally if there was any measurable difference between them. More precisely, he sought to find if there was any difference in the ratio m_G/m_I between one object and another. He hit upon side-by-side pendulums as a way to do it.

Consider a box suspended from the ceiling by a long cord of length R. Fill the box with some material, so that the box plus contents has inertial mass m_I and gravitational mass m_G. Pull the box aside and let it swing back and forth. What is the *period* (the time for one complete oscillation) of this *pendulum*?

An isolation diagram of the box plus contents is shown. Two forces act on the box (if air resistance is neglected: gravity $m_G g$ and the cord tension T. The box obeys Newton's second law $\mathbf{F} = m_I a$. In the tangential direction (perpendicular to the cord) the only force is the component of gravity $m_G g \sin\theta$, where θ is the angle of the cord from the vertical. The arc-length distance of the box from its lowest point is $s = R\theta$, so the tangential velocity and acceleration of the box are

$$v_{\text{tangential}} = \frac{ds}{dt} = R\frac{d\theta}{dt} \quad \text{and} \quad a_{\text{tangential}} = \frac{d^2 s}{dt^2} = R\frac{d^2\theta}{dt^2}.$$

The box should therefore obey $F_{\text{tangential}} = m_G g \sin\theta = m_I\, a_{\text{tangential}} = m_I\, R\frac{d^2\theta}{dt^2}$, so the angular acceleration $\frac{d^2\theta}{dt^2}$ of the box is

$$\frac{d^2\theta}{dt^2} = \left(\frac{m_G}{m_I}\right)\frac{g}{R}\sin\theta.$$

The angular acceleration obviously depends upon the ratio m_G/m_I. So if two boxes of the same size and shape (to make air resistance the same for each) swing back and forth side by side, they should stay swinging *together* if the ratio m_G/m_I is the same for each. If the ratio is *less* for one than the other, the acceleration of the first will be *less*, so it will *lag* the second in its oscillations back and forth. Newton tried this for many materials, and found that the pendulums swung together, neither one lagging behind the other.

> . . . I tried the thing in gold, silver, lead, glass, sand, common salt, wood, water, and wheat. I provided two equal wooden boxes. I filled the one with wood, and suspended an equal weight of gold (as exactly as I could) in the centre of oscillation of the other. The boxes, hung by equal threads of 11 feet, made a couple of pendulums perfectly equal in weight and figure, and equally exposed to the resistance of air: and, placing the one by the other, I observed them to play together forwards and backwards for a long while, with equal vibrations. And therefore (by Cor. I and VI, Prop. XXIV, Book II) the quantity of matter in the gold was to the quantity of matter in the wood as the action of the motive force upon all the gold to the action of the same upon all the wood; that is, as the weight of the one to the weight of the other.
>
> And by these experiments, in bodies of the same weight, one could have discovered a difference of matter less than the thousandth part of the whole.

I. Newton in *Principia* (1686), "The System of the World", paragraph 19. Originally published by the University of California Press.

15.4 The principle of equivalence

The equivalence of uniformly accelerating frames with frames at rest in uniform gravity is intimately tied up with the equality of inertial and gravitational mass. However, the equivalence of uniformly-accelerating frames and unaccelerated frames with gravity goes much farther, according to a *Principle of Equivalence* proposed by Albert Einstein.

Einstein believed that for experiments carried out entirely within a closed box (such as the cabin of a spaceship), there is *no way* to tell whether the box is at rest on a planet with uniform gravity or is in empty space undergoing uniform acceleration. Einstein proposed that the Principle of Equivalence should hold not only for experiments in mechanics, but for any experiments at all, including experiments in optics, nuclear or particle physics, thermodynamics, you name it. So far, no exceptions have been found.

A symbolic picture of the principle is shown in Fig. 3.

Fig. 3. The Principle of Equivalence (figure by A.Mittelstaedt, Am. J. Phys., 65 318 (1997)

What can we predict from the principle of equivalence?

(1) We already know we can predict that $m_G = m_I$ for all objects. If any discrepancy from this rule were observed, however small, that would disprove the principle.

(2) We know that there must be an effective gravity in the accelerating ship, which behaves just like real gravity.

(3) *Any* experiment we do entirely within a frame at rest on the ground must behave the same way in an accelerating frame without gravity, and vice versa. Sometimes one frame is easier to work in, or understand physics in, than the other, but we can firmly predict what will happen in the other frame, based on the principle of equivalence.

Suppose for example someone had never before been in a car accelerating forward when the light turns green. How might they predict what it would feel like?

The car is an accelerating frame, accelerating forward. But that is equivalent to a car at *rest*, with an effective gravity *backward*, i.e. in the opposite direction to the car's acceleration, and with a magnitude equal to the magnitude of the car's acceleration relative to the ground, as shown in Fig. 4. This effective gravity would pull a person backward, pressing the person harder into the back of the seat. (The effective gravity is of course in *addition* to the real gravity pulling downward.)

Fig. 4. The principle of equivalence applied to an accelerating car.

Sample Problem 5. A pair of "fuzzy dice" hangs from a string attached to the rear-view mirror inside a drag-racing car. After accelerating for some time, the driver notices that the string has the steady angle 17° from the vertical. What is the acceleration of the dragster?

Solution: In the accelerating frame of the car, there is an effective gravity $\mathbf{g}_{eff} = -\mathbf{a}_{car}$ directed toward the rear, in addition to the real gravity $\mathbf{g}$ directed vertically downward. The net gravity is therefore as shown, at angle 17° to the vertical so the string will hang in that direction. It follows from the triangle that $a_{car}/g = \tan 17^{\circ}$, so $a_{car} = g\tan 17^{\circ}$ $= 9.8\ \text{m/s}^2 \cdot 0.306 = 3.0\ \text{m/s}^2$.

Note: Artificial gravity may turn out to be important for long spaceflights because there is evidence that prolonged exposure to "zero gee" can contribute to a loss of muscle tone and bone mass. As we saw in Section 15.1, uniformly accelerated straight-line motion could in principle be used to provide an artificial gravity within a spaceship. However, it is not possible for spaceships to undergo substantial uniform accelerations for very long, at least if they use conventional chemical fuels. As shown in the *Special Topic* at the end of *Day Six*, the mass M of a ship (including onboard fuel) with uniform acceleration a is $M = M_0 e^{-at/u}$, dropping off exponentially with time t, where M_0 is its initial mass and u is the ex- haust velocity. If $u = 3$ km/s (typical for chemical fuel rockets) and the ship acceleration is $a = 10\ \text{m/s}^2$ (about one Earth gee), the mass remaining is already only about 1% of the initial mass in 23 minutes after blast-off. So it is not possible for such chemically fueled uniformly-accelerating rockets to provide artificial gravity for very long. A better way is needed to provide artificial gravity for prolonged spaceflights or for living in space.

15.5 A rotating space station

Following a period of uniform acceleration while we enjoyed the artificial gravity, our ship has now been drifting for several hours while we float around weightless inside.

A giant cylinder looms into view dead ahead. It slowly rotates about its axis of symmetry.

We know that the rotating frame of the cylinder is a non-inertial, accelerating frame. Is there artificial gravity within the cylinder, just as there is in the uniformly accelerating frame of a spaceship?

We enter the cylinder through an air-lock at one end, very near the rim. We find ourselves pressed against the rim just as though gravity was acting radially outward from the cylinder's rotation axis. This is similar to what happened during *Day One* in the Bubble; when the Bubble rotated we were pulled outward as though by gravity.*

We are pressed against the rim because, from the standpoint of an external inertial observer, we naturally tend to move in a straight line at constant speed, as shown in Fig. 5(a). This straight-line motion is obstructed by the rim, which pushes us toward the axis of rotation so we move in a circle from the external observer's point of view, accelerating always toward the center of the circle. To the outside inertial observer the only force on us is this normal force due to the rim, so our isolation diagram is as shown in Fig. 5(b).

Fig. 5. A rotating space station. (a) Standing on the inside rim, we are forced to move in a circle from the point of view of an external inertial observer. (b) Our isolation diagram. Note that it is the normal force due to the rim that is responsible for deflecting us from a straight-line path.

* Rotating centrifuges use this type of artificial gravity to separate chemical and biological samples.

We have defined the weight of an object to be the force exerted by the object on a scale that supports it. A scale exerts a normal force on the object to keep it in place; the object exerts an equal but opposite force on the scale. This is the weight of the object. What then is our weight within the rotating space station?

If we stand on a scale, as shown, we move in a circle according to inertial observers, so we accelerate toward the cylinder axis with acceleration $a = v^2/R = R\omega^2$, where v is the rim speed, R is the radius of the circle, and ω is the angular speed of the station.

The only force F on us is due to the scale, so from Newton's second law this force is $F = ma = mv^2/R = mR\omega^2$, directed toward the cylinder axis, where m is our mass. By Newton's third law (the force-counterforce rule), we exert an equal but opposite force on the scale, directed radially outward, away from the cylinder axis.

By definition, this force F is our weight

$$\mathbf{W} = \frac{mv^2}{R}\hat{\mathbf{r}} = mR\omega^2\,\hat{\mathbf{r}}$$

where $\hat{\mathbf{r}}$ is a unit vector (i.e., a vector of unit length) pointed radially *outward*, in the direction of increasing r. The weight of any object in the station is proportional to its mass, so we can write $\mathbf{W} = m\mathbf{g}_{\text{eff}}$, where the magnitude of the effective gravity vector $\mathbf{g}_{\text{eff}}$ is

$$g_{\text{eff}} = \frac{v^2}{r} = r\omega^2$$

(r is the distance from the center of the cylinder), and the direction of $\mathbf{g}_{\text{eff}}$ is outward, away from the rotation axis. At a given position, $\mathbf{g}_{\text{eff}}$ is the same for all objects.

The weight of an object depends upon its location within the station. The angular velocity ω of the station is everywhere the same, so the weight of an object near the center is less than it is near the rim, since the effective gravity has the magnitude $g_{\text{eff}} = r\omega^2$.

Colonists in a huge rotating space colony could build a small mountain whose base is at the rim and whose summit is at the center of the colony, so that mountaineers would experience less and less gravity as they ascended, a rewarding way to climb! If zero-gee experiments or manufacturing were required, they could be carried out in the center of the colony, while residents could live for the most part on the rim.

Even though the artificial gravity felt by colonists living on the inside rim of a rotating colony could feel the same as ordinary gravity on the Earth, there are some obvious differences in the environment. For example, in a rotating colony people could look straight overhead and see other colonists walking around upside down on the opposite side of the rim.

The behavior of rapidly moving objects would also be different than on Earth. For example, suppose an object is thrown straight up in the air, above the thrower. On Earth the object falls back pretty much straight down. What happens in the colony?

Sample Problem 6. A cylindrical space colony of radius R rotates with period T. A colonist standing on the rim throws a ball straight "up" toward the rotation axis, with speed $v = 2\pi R/T$.

(a) Sketch the trajectory of the ball as seen by an outside inertial observer.

(b) Find the time required for the ball to return to the rim, as a multiple of T.

(c) How far along the rim must the colonist run, relative to the rim itself, to catch the ball?

(d) Sketch the path of the ball as seen by observers at rest in the colony.

Solution: (a) As seen by an inertial observer, the rim of the colony moves with speed $v = \dfrac{\text{distance}}{\text{time}} = \dfrac{2\pi R}{T}$, the circumference divided by the period. If the colonist throws the ball toward the rotation axis with this same speed, then from the point of view of an outside inertial observer the ball moves at a 45° angle as shown. In the inertial frame the ball subsequently moves in a straight line at constant speed, because there is no force on it. The ball then intersects the rim one-quarter of the way around, as shown.

(b) The ball's speed in this frame is $v = (v_x^2 + v_y^2)^{1/2} = (2\, v_x^2)^{1/2} = \sqrt{2}\,\dfrac{2\pi R}{T}$, so the time required for the ball to reach (i.e., "fall to") the rim is

$$t = \frac{\text{distance}}{\text{speed}} = \frac{\sqrt{2}\,R}{\sqrt{2}\,(2\pi R/T)} = \frac{T}{2\pi}.$$

(c) During this time the rim itself turns a distance $d = \text{speed} \cdot \text{time} = \dfrac{2\pi R}{T}\left(\dfrac{T}{2\pi}\right) = R$, so the ball strikes the rim a distance

$$\left(\frac{2\pi R}{4} - R\right) = \frac{\pi}{2}R - R = 0.57\,R$$

from the colonist. This is how far the colonist has to run to catch the ball, even though the ball was thrown vertically upward in the colony frame.

(d) The trajectory of the ball as seen by the colonist is as shown. Note that it rises vertically at the beginning, that its highest point is a distance $R/\sqrt{2}$ from the colony center (the same as in the inertial frame) and that as it arrives at the rim it falls vertically (perpendicular to the rim itself at that point), a distance $0.57\,R$ around the rim from where it started.

If a ball is thrown upward only a short distance, i. e., if its initial speed in the colony is only a small fraction of the colony's rim speed, the ball will behave more nearly like a ball thrown on Earth, rising almost straight up and falling almost straight down.

Sample Problem 7. A rotating cylindrical resort hotel is constructed, featuring a low-gravity swimming pool extending around much of the rim, as shown. (The illustration on the facing page is by Bob McCall, in an article by Timothy Ferris in *The New York Times Magazine*, Nov 28, 1999. The background for this problem was taken from Ferris' article.) The hotel has radius R and rotation period T, and a diving board is placed a distance $R/2$ from the rim. A guest steps off the board.

(a) Sketch the path of the guest in the frame of an outside inertial observer.

(b) How long does it take the guest to reach the pool?

(c) A friend is treading water beneath the diving board. How far from the friend will the diving guest enter the water, measured around the rim?

Solution: (a) As seen by an outside inertial observer looking in through one end of the hotel, the rim moves with speed $v_{\text{rim}} = \dfrac{2\pi R}{T}$, and the diver (before stepping off) has speed $v_0 = \dfrac{\pi R}{T}$, since the diver is at distance $R/2$ from the axis of rotation. After stepping off, no forces act on the diver, so the diver subsequently moves in a straight line at constant speed, as shown.

(b) As seen in the sketch above, in the inertial frame the diver moves along one leg of a right triangle, a distance $d = \dfrac{\sqrt{3}}{2}R$, using the Pythagorean theorem. The speed of the diver is $v = v_0 = \dfrac{\pi R}{T}$, so the time to reach the pool is $t = d/v = \dfrac{\sqrt{3}}{2}R \,/\, \dfrac{\pi R}{T} = \dfrac{\sqrt{3}}{2\pi}T$.

(c) The diver strikes the pool at a point an angle $\theta = 60^\circ = \pi/3$ radians around the rim from the point initially directly below the board, as can be seen in the triangle above. Measured around the rim, the distance is therefore $s_{\text{diver}} = R\theta = \pi R/3$. This is not the distance from the friend in the pool, however, because in the inertial frame the friend has been moving around a distance $s_{\text{friend}} = v_{\text{rim}}t$, where $t = \dfrac{\sqrt{3}}{2\pi}T$ is the duration of the dive. That is, the friend in the water has moved a distance $s_{\text{friend}} = \dfrac{2\pi R}{T}\dfrac{\sqrt{3}}{2\pi}T = \sqrt{3}R$. As the diver enters the water, the distance between the diver and friend is therefore $\Delta s = s_{\text{friend}} - s_{\text{diver}} = \left(\sqrt{3} - \dfrac{\pi}{3}\right)R = 0.685\,R$. The friend travels farther than the diver, so the diver enters the pool to the "left" of the friend.

$$\mathbf{a}_n = \frac{(\mathbf{d}_{n+1} - 2\mathbf{d}_n + \mathbf{d}_{n+1})}{\Delta t^2} \tag{1.68}$$

Time Integration for Hyperbolic Equations. Consider the first order wave equation (Euler equation) of the form,

$$\frac{\partial u}{\partial t} + a\frac{\partial u}{\partial x} = 0, \quad a > 0 \tag{1.69}$$

Euler's forward time and forward space approximation

$$\frac{u_i^{n+1} - u_i^n}{\Delta t} = -a\frac{u_{i+1}^n - u_i^n}{\Delta x} \tag{1.70}$$

where n is the time step, and i is a typical spatial nodal point.

Midpoint Leapfrog Method The so-called leapfrog method uses three time levels of information, n-1, n, and n+1.

$$\frac{u_i^{n+1} - u_i^{n-1}}{2\Delta t} = -a\frac{u_{i+1}^n - u_{i-1}^n}{2\Delta x} \tag{1.71}$$

1.2.8 Voronoi Diagram and Delaunay Tessellation

The Voronoi diagram is a fundamental structure in computational geometry, because the Voronoi diagram and its dual Delaunay tessellation are one of the most fundamental and useful topological (geometric) structures that connect a set of randomly distributed particles. Today, some of the best finite element mesh generators, or mesh generation algorithms are based on the Voronoi diagram and Delaunay tessellation. Apparently, some of the meshfree discretizations are also based on local properties of the Voronoi diagram

Fig. 1.2. Voronoi diagram of a set of seven nodes: (a) Delaunay triangulation DT(N), and (b) Natural neighbor circum-circles.

and Delaunay tessellation. For simplicity, we only outline the main properties of the Voronoi diagram and Delaunay tessellation in a two-dimensional Euclidean space $\mathbb{R}^2$, though the theory is, however, applicable in a general d-dimensional framework.

Consider a set of distinct nodes $\Lambda = \{1, 2, \cdots, I, \cdots, NP\}$ in $\mathbb{R}^2$. The Voronoi diagram (or 1st-order Voronoi diagram) of the point set Λ is a subdivision of the plane into regions (tiles) $\mathbb{R}^2 \subset \bigcup_{I \in \Lambda} \{T_I\}$, where each T_I (tile) is either closed and convex (in interior), or unbounded (at boundary). The tile T_I is defined as a region that contains a node n_I, such that any point in T_I is closer to I than to any other nodal point $J \in \Lambda$ $(J \neq I)$,

$$T_I = \left\{ \mathbf{x} \in \mathbb{R}^2 : d(\boldsymbol{x}, \boldsymbol{x}_I) \leq d(\boldsymbol{x}, \boldsymbol{x}_J),\ \forall I, J \in \lambda \right\} \tag{1.72}$$

where $d(\boldsymbol{x}, \boldsymbol{x}_I) := \|\boldsymbol{x} - \boldsymbol{x}_I\|$ is the Euclidean norm.

The Voronoi cell for node A and the Voronoi diagram for a set of seven nodes are shown in Fig. 1.2. In Fig. 1.2, it is shown that each Voronoi cell T_I is the intersection of finitely many open half-spaces, each being delimited by the perpendicular bisector of the line joining nodes I and J $(J \neq I)$. Denote the convex hull, $CH(\Lambda)$, as the smallest convex set containing the NP nodes. For all nodes I that are inside the convex hull, Voronoi cells are closed and convex, while the cells associated with nodes on the boundary of the convex hull are unbounded.

The Delaunay triangulation, which is the straight-line dual of the Voronoi diagram, is constructed by connecting the nodes whose Voronoi cells have common boundaries. The duality between the Voronoi diagram and Delaunay triangulation refers to the fact that there is a Delaunay edge between two nodes in the plane if only their Voronoi cells share a common edge. Among all triangulations, the Delaunay triangulation maximizes the minimum angle in each individual triangle, which is a desired property in finite element tri-

The Delaunay triangulation, which is the straight-line dual of the Voronoi diagram, is constructed by connecting the nodes whose Voronoi cells have common boundaries. The duality between the Voronoi diagram and Delaunay triangulation refers to the fact that there is a Delaunay edge between two nodes in the plane if only their Voronoi cells share a common edge.

angulation. Another important property of Delaunay triangles is the *empty circumcircle criterion* (Lawson [1977]), which states that if $DT(I, J, K)$ is any Delaunay triangle of the nodal set Λ, then the circumcircle of DT contains only three nodes (I,J,K) in Λ that are the vortices of the Delaunay triangle. In natural neighbor interpolation, these circles are known as natural neighbor circumcircles. Fig. 1.2 (b) shows natural neighbor circumcircles and the associated Delaunay triangulation.

A detailed description of the properties and applications of the Voronoi diagrams can be found in Boots [1966], and Okabe, Boots, and Sugihara [1992].

A discussion on randomized algorithms to compute Voronoi diagrams and Delaunay tessellations can be found in Mulmuley (1994). For applying Voronoi diagram to finite element mesh generation, readers may consult Fortune (1995).

6.5 Globally Conforming I^m/C^n Hierarchy II

The globally conforming I^m/C^n hierarchy constructed in the previous section has its limitations. The globally conforming hierarchy is in fact $I^m/C^n/P^m$, i.e. $k = m$. This means that the reproducing property of the interpolant is limited by the interpolation index order m, or the enrichment order. It can only reproduce complete m-th order polynomials. In order to achieve higher order accuracy, another (the second) globally conforming $I^m/C^n/P^k(k \geq m)$ hierarchy is proposed. This interpolation hierarchy can reproduce a complete kth order polynomials with $k \geq m$.

6.5.1 Construction

Assume that there exists a set of Hermite type global polynomials, $\{\psi_{e,i}^{(0)}, \psi_{e,i}^{(1)}, \cdots, \psi_{e,i}^{(m)}\}$, such that within the element e, they can reproduce λ-th order polynomials, i.e.

$$\sum_{i \in \Lambda_e} \left\{ \psi_{e,i}^{(0)}(\boldsymbol{x})\boldsymbol{x}_i^{\lambda} + \lambda\psi_{e,i}^{(1)}(\boldsymbol{x})\boldsymbol{x}_i^{\lambda-1} + \cdots + \frac{\lambda!}{(\lambda-m)!}\psi_{e,i}^{(m)}(\boldsymbol{x})\boldsymbol{x}_i^{\lambda-m} \right\} = \boldsymbol{x}^{\lambda} \ , \quad |\lambda| \leq k \tag{6.177}$$

Assume that the mesh topology has a subjective connectivity map such that

$$\Lambda_E \times \Lambda_e \to \Lambda_P : (e_1, i_1), \cdots, (e_\ell, i_\ell) \to I \ . \tag{6.178}$$

The global RKEM basis functions are constructed as follows,

$$\Psi_I^{(0)}(\boldsymbol{x}) = \sum_{k=1}^{\ell} \Big(\sum_{j \in \Lambda_{e_k}} \mathcal{K}_{e_k,j}^{\rho}(\boldsymbol{x}) \Delta V_{e_k,j} \Big) \psi_{e_k,i_k}^{(0)}(\boldsymbol{x})$$

$$\Psi_I^{(1)}(\boldsymbol{x}) = \sum_{k=1}^{\ell} \Big(\sum_{j \in \Lambda_{e_k}} \mathcal{K}_{e_k,j}^{\rho}(\boldsymbol{x}) \Delta V_{e_k,j} \Big) \psi_{e_k,i_k}^{(1)}(\boldsymbol{x})$$

$$\cdots\cdots \tag{6.179}$$

$$\Psi_I^{(m)}(\boldsymbol{x}) = \sum_{k=1}^{\ell} \Big(\sum_{j \in \Lambda_{e_k}} \mathcal{K}_{e_k,j}^{\rho}(\boldsymbol{x}) \Delta V_{e_k,j} \Big) \psi_{e_k,i_k}^{(m)}(\boldsymbol{x}) \tag{6.180}$$

where $I \in \Lambda_P$ and

$$\underset{e \in \Lambda_E}{\mathbf{A}} \sum_{j \in \Lambda_e} \Big(\mathcal{K}_{e,j}^{\rho}(\boldsymbol{x}) \Delta V_{e,j} \Big) = 1. \tag{6.181}$$

Again, the proposed RKEM I^m/C^n interpolation scheme can be written as

$$I^m f = \sum_{I \in \Lambda_P} \left(\Psi_I^{(0)}(\boldsymbol{x}) f_I + \Psi_I^{(0)}(\boldsymbol{x}) Df \Big|_I + \cdots + \Psi_I^{(m)}(\boldsymbol{x}) D^m f \Big|_I \right) \quad (6.182)$$

The main properties of this globally conforming I^m/C^n hierarchy are summarized in the following proposition.

Proposition 6.5.1. *Assume that* $\exists\ \{\psi_{e,i}^{(0)}, \psi_{e,i}^{(1)}, \cdots \psi_{e,i}^{(m)}\}$, $\forall e \in \Lambda_E, i \in \Lambda_e$, *such that*

1.

$$D^\alpha \psi_{e,i}^{(\beta)} \Big|_{\boldsymbol{x}=\boldsymbol{x}_j} = \delta_{\alpha\beta}\delta_{ij}, \quad |\alpha|, |\beta| \le m, \quad \text{and} \quad i, j \in \Lambda_e; \quad (6.183)$$

2.

$$\sum_{i \in \Lambda_e} \left\{ \psi_{e,i}^{(0)}(\boldsymbol{x}) \boldsymbol{x}_i^\lambda + \lambda \psi_{e,i}^{(1)}(\boldsymbol{x}) \boldsymbol{x}_i^{\lambda-1} + \cdots + \frac{\lambda!}{(\lambda-m)!} \psi_{e,i}^{(m)}(\boldsymbol{x}) \boldsymbol{x}_i^{\lambda-m} \right\} = x^\lambda \ . \quad (6.184)$$

Consider the local-global connectivity map for a given mesh,

$$\Lambda_E \times \Lambda_e \to \Lambda_P : (e_1, i_1) \cdots (e_k, i_k) \cdots (e_\ell, i_\ell) \to I \ . \quad (6.185)$$

We construct the following hybrid meshfree/FEM shape functions,

$$\Psi_I^{(0)}(\boldsymbol{x}) = \sum_{k=1}^{\ell} \Big(\sum_{j \in \Lambda_{e_k}} \mathcal{K}_{e_k,j}^\rho(\boldsymbol{x}) \Delta V_{e_k,j} \Big) \psi_{e_k,i_k}^{(0)}(\boldsymbol{x})$$

$$\Psi_I^{(1)}(\boldsymbol{x}) = \sum_{k=1}^{\ell} \Big(\sum_{j \in \Lambda_{e_k}} \mathcal{K}_{e_k,j}^\rho(\boldsymbol{x}) \Delta V_{e_k,j} \Big) \psi_{e_k,i_k}^{(1)}(\boldsymbol{x})$$

$$\cdots\cdots \quad (6.186)$$

$$\Psi_I^{(m)}(\boldsymbol{x}) = \sum_{k=1}^{\ell} \Big(\sum_{j \in \Lambda_{e_k}} \mathcal{K}_{e_k,j}^\rho(\boldsymbol{x}) \Delta V_{e_k,j} \Big) \psi_{e_k,i_k}^{(m)}(\boldsymbol{x}) \quad (6.187)$$

where $I \in \Lambda_P$.

Then the interpolation scheme (6.182) has the following properties,

1. $D^\alpha \Psi_I^{(\beta)} \Big|_{\boldsymbol{x}=\boldsymbol{x}_J} = \delta_{\alpha\beta}\delta_{IJ}, \quad I, J \in \Lambda_P, |\alpha|, |\beta| \le m;$
2. $I^m \boldsymbol{x}^\lambda = \boldsymbol{x}^\lambda, \ \forall \boldsymbol{x} \in \Omega, \ |\lambda| \le k.$

Proof:

1. We first show $D^\alpha \Psi_I^{(\beta)} \Big|_{\boldsymbol{x}=\boldsymbol{x}_J} = \delta_{\alpha\beta}\delta_{IJ}, \quad \forall I, J \in \Lambda_P$. By definition,

$$\Psi_I^{(\beta)}(\boldsymbol{x}) = \sum_{k=1}^{\ell}\Big(\sum_{j\in\Lambda_{e_k}} \mathcal{K}^{\rho}_{e_k,j}(\boldsymbol{x})\Delta V_{e_k,j}\Big)\psi^{(\beta)}_{e_k,i_k}$$

$$\Rightarrow D^{\alpha}\Psi_I^{(\beta)}(\boldsymbol{x}) = \sum_{|\gamma|\le|\alpha|}\left\{\binom{\alpha}{\gamma}\sum_{k=1}^{\ell} D^{\alpha-\gamma}\Big(\sum_{j\in\Lambda_{e_k}} \mathcal{K}^{\rho}_{e_k,j}(\boldsymbol{x})\Delta V_{e_k,j}\Big)D^{\gamma}\psi^{(\beta)}_{e_k,i_k}\right\}\Big|_{\boldsymbol{x}=\boldsymbol{x}_J}$$

If $\boldsymbol{x}_J \in \Omega_{e_k}$, based on (6.183) $D^{\gamma}\psi^{(\beta)}_{e_k,i_k}(\boldsymbol{x}_J) = \delta_{\alpha\beta}\delta_{IJ}$. If $\boldsymbol{x}_J \notin \Omega_{e_k}$, the restriction on the support size of meshfree kernels requires that

$$\mathcal{K}^{\rho}_{e_k,i_k}(\boldsymbol{x}_J) \equiv 0 \tag{6.188}$$

Therefore,

$$D^{\alpha}\Psi_I^{(\beta)}(\boldsymbol{x}) = \sum_{|\gamma|\le|\alpha|}\left\{\binom{\alpha}{\gamma}\sum_{k=1}^{\ell} D^{\alpha-\gamma}\Big(\sum_{j\in\Lambda_{e_k}} \mathcal{K}^{\rho}_{e_k,j}(\boldsymbol{x})\Delta V_{e_k,j}\Big)\delta_{IJ}\delta_{\gamma\beta}\right\}\Big|_{\boldsymbol{x}=\boldsymbol{x}_J}$$

Since

$$\sum_{k=1}^{\ell}\Big(\sum_{j\in\Lambda_{e_k}} \mathcal{K}^{\rho}_{e_k,j}(\boldsymbol{x})\Delta V_{e_k,j}\Big) = 1, \tag{6.190}$$

if $|\alpha-\gamma| > 0$,

$$\sum_{k=1}^{\ell} D^{\alpha-\gamma}\Big(\sum_{j\in\Lambda_{e_k}} \mathcal{K}^{\rho}_{e_k,j}(\boldsymbol{x})\Delta V_{e_k,j}\Big) = 0. \tag{6.191}$$

That is

$$\binom{\alpha}{\gamma}\sum_{k=1}^{\ell} D^{\alpha-\gamma}\Big(\sum_{j\in\Lambda_{e_k}} \mathcal{K}^{\rho}_{e_k,j}(\boldsymbol{x})\Delta V_{e_k,j}\Big)\Big|_{\boldsymbol{x}=\boldsymbol{x}_J} = \delta_{\alpha\gamma} \tag{6.192}$$

Hence

$$D^{\alpha}\Psi_I^{(\beta)}(\boldsymbol{x})\Big|_{\boldsymbol{x}=\boldsymbol{x}_J} = \delta_{\alpha\beta}\delta_{IJ}\ . \tag{6.193}$$

Next, we show $\mathcal{I}\boldsymbol{x}^{\lambda} = \boldsymbol{x}^{\lambda}$, $|\lambda| \le k$. Note that here $|\lambda| < k$. $|\lambda|$ can be greater than m and in most cases it is. This is the reason why the second I^m/C^n hierarchy is more accurate.

Based on the construction,

$$\begin{aligned}
\mathcal{I}^m \boldsymbol{x}^\lambda &= \sum_{I\in\Lambda_P}\Big(\Psi_I^{(0)}(\boldsymbol{x})\boldsymbol{x}_I^\lambda + \Psi_I^{(1)}(\boldsymbol{x})\lambda\boldsymbol{x}_I^{<\lambda-1>} + \cdots + \frac{\lambda!}{(\lambda-\gamma)!}\Psi_I^{(\gamma)}(\boldsymbol{x})\boldsymbol{x}_I^{<\lambda-\gamma>} \\
&\quad + \cdots + \frac{\lambda!}{(\lambda-m)!}\Psi_I^{(m)}(\boldsymbol{x})\boldsymbol{x}_I^{<\lambda-m>}\Big) \\
&= \mathop{\mathbf{A}}_{e\in\Lambda_E}\Bigg(\sum_{j\in\Lambda_e}\Big(\mathcal{K}_{e,j}^\rho \Delta V_{e,j}\Big)\sum_{i\in\Lambda_e}\Big(\psi_{e,i}^{(0)}\boldsymbol{x}_{e,i}^\lambda + \psi_{e,i}^{(1)}\boldsymbol{x}_{e,i}^{\lambda-1} + \cdots \\
&\quad + \frac{\lambda!}{(\lambda-\gamma)!}\psi_{e,i}^{(\gamma)}\boldsymbol{x}_{e,i}^{<\lambda-\gamma>} + \cdots + \frac{\lambda!}{(\lambda-m)!}\psi_{e,i}^{(m)}\boldsymbol{x}_{e,i}^{<\lambda-m>}\Big)\Bigg) \qquad (6.194)
\end{aligned}$$

Based on the assumptions that

1.

$$\sum_{i\in\Lambda_e}\Big(\psi_{e,i}^{(0)}\boldsymbol{x}_{e,i}^\lambda + \cdots + \frac{\lambda!}{(\lambda-\gamma)!}\psi_{e,i}^{(\gamma)}\boldsymbol{x}_{e,i}^{<\lambda-\gamma>} + \cdots + \frac{\lambda!}{(\lambda-m)!}\psi_{e,i}^{(m)}\boldsymbol{x}_{e,i}^{<\lambda-m>}\Big) = \boldsymbol{x}^\lambda;$$

2.

$$\mathop{\mathbf{A}}_{e\in\Lambda_E}\sum_{j\in\Lambda_e}\Big(\mathcal{K}_{e,j}^\rho \Delta V_{e,j}\Big) = 1.$$

We conclude that

$$\mathcal{I}^m \boldsymbol{x}^\lambda = \mathop{\mathbf{A}}_{e\in\Lambda_E}\sum_{j\in\Lambda_e}\Big(\mathcal{K}_{e,j}^\rho \Delta V_{e,j}\Big)\boldsymbol{x}^\lambda = \boldsymbol{x}^\lambda\ . \qquad (6.197)$$

♣

6.5.2 1D Example: An $I^1/C^4/P^3$ Interpolant

For tutorial purpose, we first construct an 1D $I^1/C^4/P^3$ hybrid RKEM interpolant.

Consider a two nodes element, $e \to [x_e, x_{e+1}]$. Let $\xi = (x - x_e)/L_e$ where $L_e = x_{e+1} - x_e$. We choose 1D cubic Hermite polynomials as the global partition polynomials, which are

$$\begin{aligned}
&\psi_{e,1}^{(0)}(\xi) = 1 - 3\xi^2 + 2\xi^3, \quad \psi_{e,2}^{(0)}(\xi) = 3\xi^2 - 2\xi^3, \\
&\psi_{e,1}^{(1)}(\xi) = L_e(\xi - 2\xi^2 + \xi^3), \quad \psi_{e,2}^{(1)}(\xi) = L_e(-\xi^2 + \xi^3)\ .
\end{aligned}$$

For a sufficient smooth function $f(x)$, the hybrid RKEM interpolant is expressed as

Fig. 6.22. The global shape functions of 1D $I^1/C^4/P^3$ element: (a) $\Psi_I^{(0)}(\boldsymbol{x})$; (b) $\Psi_I^{(1)}(\boldsymbol{x})$; (c) $d\Psi_I^{(0)}/dx$; (d) $d\Psi_I^{(1)}/dx$.

$$\begin{aligned}\mathcal{I}^1 f(x) &= \mathop{\mathbf{A}}_{e\in\Lambda_E}\Bigg\{\Big(\sum_{j=1}^{2}\mathcal{K}_{e,j}^{\rho}(x)\Delta x_{e,j}\Big)\Big(\sum_{i=1}^{2}\psi_{e,i}^{(0)}(x)f_{e,i}\Big)\\ &\quad+\Big(\sum_{j=1}^{2}\mathcal{K}_{e,j}^{\rho}(x)\Delta x_{e,j}\Big)\Big(\sum_{i=1}^{2}\psi_{e,i}^{(1)}(x)f'_{e,i}\Big)\Bigg\}\\ &= \sum_{I\in\Lambda_P}\Big(\Psi_I^{(0)}(x)f_I+\Psi_I^{(1)}(x)f'_I\Big)\end{aligned} \tag{6.198}$$

Suppose that the mesh connectivity map has the form,

$$\Lambda_E\times\Lambda_e\to\Lambda_P:(e_1,i_1),(e_2,i_2)\to I$$

The global RKEM shape functions are

$$\Psi_I^{(0)}(x)=\sum_{k=1}^{2}\Big(\sum_{j\in\Lambda_{e_k}}\mathcal{K}_{e_k,j}^{\rho}(x)\Delta x_{e_k,j}\Big)\psi_{e_k,i_k}^{(0)} \tag{6.199}$$

$$\Psi_I^{(1)}(x)=\sum_{k=1}^{2}\Big(\sum_{j\in\Lambda_{e_k}}\mathcal{K}_{e_k,j}^{\rho}(x)\Delta x_{e_k,j}\Big)\psi_{e_k,i_k}^{(1)} \tag{6.200}$$

In order that $\Psi_I^{(i)} \in C^4(\Omega), i = 1, 2$ and $I \in \Lambda_E$, we choose the fifth order spline function as the window function of the meshfree kernel. The global shape functions and their first order derivatives are plotted in Fig. 6.22.

6.5.3 2D Example I: Compatible Gallagher Element

In this example, we choose the global partition polynomials derived from the previous 2D incompatible rectangular element, or Gallagher element.[174]

Fig. 6.23. A globally conforming Gallagher element.

To derive the global partition polynomials, we consider the following element interpolation field in a four nodes rectangular element,

$$\begin{aligned}\mathcal{I}_{loc} f &= \sum_{i=1}^{4} \psi_{e,i}^{(00)}(\boldsymbol{x}) f_{e,i} + \psi_{e,i}^{(10)}(\boldsymbol{x}) \frac{\partial f}{\partial x}\Big|_{e,i} + \psi_{e,i}^{(01)}(\boldsymbol{x}) \frac{\partial f}{\partial y}\Big|_{e,i} \\ &= \boldsymbol{\psi}^T \mathbf{f} \end{aligned} \tag{6.201}$$

where $\boldsymbol{\psi}$ is denoted as the local shape function array and vector $\mathbf{f}$ is the nodal data array, i.e.

$$\begin{aligned}\boldsymbol{\psi}^T = \{&\psi_{e,1}^{(00)}, \psi_{e,1}^{(10)}, \psi_{e,1}^{(01)}, \psi_{e,2}^{(00)}, \psi_{e,2}^{(10)}, \psi_{e,2}^{(01)}, \psi_{e,3}^{(00)}, \psi_{e,3}^{(10)}, \psi_{e,3}^{(01)} \psi_{e,4}^{(00)}, \\ &\psi_{e,4}^{(10)}, \psi_{e,4}^{(01)}\} \end{aligned} \tag{6.202}$$

$$\begin{aligned}\mathbf{f}^T = \{&f_{e1}, f_{e1,x}, f_{e1,y}, f_{e2}, f_{e2,x}, f_{e2,y}, f_{e3}, f_{e3,x}, f_{e3,y}, \\ &f_{e4}, f_{e4,x}, f_{e4,y}\} \end{aligned} \tag{6.203}$$

Based on Przemieniecki,[377] we have the explicit expressions for the chosen global partition polynomials,

Obs.: Gallagher element – estudar em forma curva.

$$\boldsymbol{\psi}^T = \begin{bmatrix} 1-\xi\eta-(3-2\xi)\xi^2(1-\eta)-(1-\xi)(3-2\eta)\eta^2 \\ (1-\xi)\eta(1-\eta)^2\ell_{ey} \\ -\xi(1-\xi)^2(1-\eta)\ell_{ex} \\ (1-\xi)(3-2\eta)\eta^2+\xi(1-\xi)(1-2\xi)\eta \\ -(1-\xi)(1-\eta)\eta^2\ell_{ey} \\ -\xi(1-\xi)^2\eta\ell_{ex} \\ (3-2\xi)\xi^2\eta-\xi\eta(1-\eta)(1-2\eta) \\ -\xi(1-\eta)\eta^2\ell_{ey} \\ (1-\xi)\xi^2\eta\ell_{ex} \\ (3-2\xi)\xi^2(1-\eta)+\xi\eta(1-\eta)(1-2\eta) \\ \xi\eta(1-\eta)^2\ell_{ey} \\ (1-\xi)\xi^2(1-\eta)\ell_{ex} \end{bmatrix} \tag{6.204}$$

where $-\infty < \xi, \eta < \infty$.

Assume that the mesh connectivity map is,

$$\Lambda_E \times \Lambda_e \to \Lambda_P : (e_1, i_1) \cdots (e_\ell, i_\ell) \to I \ .$$

The RKEM global shape function for the rectangular can be expressed as follows:

$$\Psi_I^{(\alpha)}(\boldsymbol{x}) = \sum_{k=1}^{\ell} \sum_{j \in \Lambda_{e_k}} \left(\mathcal{K}^{\rho}_{e_k,j}(\boldsymbol{x}) \Delta V_{e_k,j} \right) \psi^{(\alpha)}_{e_k,i_k}(\boldsymbol{x}) \ . \tag{6.205}$$

6.5.4 2D Example II: $T12P3I(4/3)$ Triangle Element

The above rectangular element can not discretize an arbitrary domain. Here, we propose a two-dimensional globally conforming, bilinear, 12 degrees of freedom triangle element. It is illustrated in Fig. 6.24. The notation $I^{4/3}$ means that at each nodal point we interpolate the unknown function, say $f(x, y)$, its two first order derivatives, $\dfrac{\partial f}{\partial x}$ and $\dfrac{\partial f}{\partial x}$ and its mixed derivative, $\dfrac{\partial^2 f}{\partial x \partial y}$, which is one-third of the second derivatives. We denote the one-third of second derivative as a cross in Fig. 6.24. Since we interpolant one third of the second derivatives, the interpolation scheme is neither I^1 nor I^2. We denote it as $I^{(1+1/3)} = I^{(4/3)}$.

The global partition polynomials in an element can form a local interpolation,

$$\begin{aligned} \mathcal{I}_{ele} f &= \sum_{i=1}^{3} \left(\psi^{(00)}_{e,i} f_{e,i} + \psi^{(10)}_{e,i} \frac{\partial f}{\partial x}\Big|_{(e,i)} + \psi^{(01)}_{e,i} \frac{\partial f}{\partial y}\Big|_{(e,i)} + \psi^{(11)}_{e,i} \frac{\partial^2 f}{\partial x \partial y}\Big|_{(e,i)} \right) \\ &= c_1 + c_2 x + c_3 y + c_4 x^2 + c_5 xy + c_6 y^2 + c_7 x^3 + c_8 x^2 y + c_9 xy^2 \\ &\quad + c_{10} y^3 + c_{11} x^2 (x^2 + xy + y^2) + c_{12} y^2 (x^2 + xy + y^2) \end{aligned} \tag{6.206}$$

Fig. 6.24. An bilinear triangle (T12P3I4/3) element.

To link the nodal data with constants,$c's$, we define vectors, $\boldsymbol{\psi}$, $\mathbf{f}$, $\mathbf{p}$, and $\mathbf{c}$:

$$\begin{aligned}
\boldsymbol{\psi}_e^T(\boldsymbol{x}) &:= \{\psi_{e,1}^{(00)}, \psi_{e,1}^{(10)}, \psi_{e,1}^{(01)}, \psi_{e,1}^{(11)}, \psi_{e,2}^{(00)}, \psi_{e,2}^{(10)}, \psi_{e,2}^{(01)}, \psi_{e,2}^{(11)}, \\
&\quad \psi_{e,3}^{(00)}, \psi_{e,3}^{(10)}, \psi_{e,3}^{(01)}, \ \psi_{e,3}^{(11)}\} && (6.207)\\
\mathbf{f}_e^T &:= \{f_1, f_{1x}, f_{1y}, f_{1xy}, f_2, f_{2x}, f_{2y}, f_{2xy}, f_3, f_{3x}, f_{3y}, f_{3xy}\}_e && (6.208)\\
\mathbf{p}^T(\boldsymbol{x}) &:= \{1, x, y, x^2, xy, y^2, x^3, x^2y, xy^2, y^3, x^2(x^2+xy+y^2), \\
&\quad y^2(x^2+xy+y^2)\} && (6.209)\\
\mathbf{c}_e^T &:= \{c_1, c_2, c_3, c_4, c_5, c_6, c_7, c_8, c_9, c_{10}, c_{11}, c_{12}\}_e && (6.210)
\end{aligned}$$

We can write that

$$\mathcal{I}_{loc} f = \boldsymbol{\psi}_e^T \mathbf{f}_e = \mathbf{p}^T \mathbf{c}_e. \tag{6.211}$$

The nodal values are related with coefficients c's by a set of 12 simultaneous linear algebraic equations

$$\mathbf{f}_e = \mathbf{C}_e \mathbf{c}_e \tag{6.212}$$

where matrix $\mathbf{C}_e$ is defined by Eq. (6.213).

One can then find vector $\mathbf{c}_e$ by solving the linear algebraic equation,

$$\mathbf{c}_e = \mathbf{C}_e^{-1} \mathbf{f} \tag{6.214}$$

Then, the global partition polynomials can be found as

$$\boldsymbol{\psi}_e(\boldsymbol{x}) = \mathbf{C}_e^{-T} \mathbf{p}(\boldsymbol{x}) \tag{6.215}$$

Assume that the mesh connectivity map is as usual

$$\Lambda_E \times \Lambda_e \to \Lambda_P : (e_1, i_1) \cdots (e_\ell, i_\ell) \to I \ . \tag{6.216}$$

$$
\mathbf{C}_e = \begin{vmatrix}
1 & x_1 & y_1 & x_1^2 & x_1y_1 & y_1^2 & x_1^3 & x_1^2y_1 & x_1y_1^2 & y_1^3 & x_1^2(x_1^2+x_1y_1+y_1^2) & y_1^2(x_1^2+x_1y_1+y_1^2) \\
0 & 1 & 0 & 2x_1 & y_1 & 0 & 3x_1^2 & 2x_1y_1 & y_1^2 & 0 & x_1(4x_1^2+3x_1y_1+2y_1^2) & y_1^2(2x_1+y_1) \\
0 & 0 & 1 & 0 & x_1 & 2y_1 & 0 & x_1^2 & 2x_1y_1 & 3y_1^2 & x_1^2(x_1+2y_1) & y_1(4y_1^2+3x_1y_1+2x_1^2) \\
0 & 0 & 0 & 0 & 1 & 0 & 0 & 2x_1 & 2y_1 & 0 & 3x_1^2+4x_1y_1 & 3y_1^2+4x_1y_1 \\
1 & x_2 & y_2 & x_2^2 & x_2y_2 & y_2^2 & x_2^3 & x_2^2y_2 & x_2y_2^2 & y_2^3 & x_2^2(x_2^2+x_2y_2+y_2^2) & y_2^2(x_2^2+x_2y_2+y_2^2) \\
0 & 1 & 0 & 2x_2 & y_2 & 0 & 3x_2^2 & 2x_2y_2 & y_2^2 & 0 & x_2(4x_2^2+3x_2y_2+2y_2^2) & y_2^2(2x_2+y_2) \\
0 & 0 & 1 & 0 & x_2 & 2y_2 & 0 & x_2^2 & 2x_2y_2 & 3y_2^2 & x_2^2(x_2+2y_2) & y_2(4y_2^2+3x_2y_2+2x_2^2) \\
0 & 0 & 0 & 0 & 1 & 0 & 0 & 2x_2 & 2y_2 & 0 & 3x_2^2+4x_2y_2 & 3y_2^2+4x_2y_2 \\
1 & x_3 & y_3 & x_3^2 & x_3y_3 & y_3^2 & x_3^3 & x_3^2y_3 & x_3y_3^2 & y_3^3 & x_3^2(x_3^2+x_3y_3+y_3^2) & y_3^2(x_3^2+x_3y_3+y_3^2) \\
0 & 1 & 0 & 2x_3 & y_3 & 0 & 3x_3^2 & 2x_3y_3 & y_3^2 & 0 & x_3(4x_3^2+3x_3y_3+2y_3^2) & y_3^2(2x_3+y_3) \\
0 & 0 & 1 & 0 & x_3 & 2y_3 & 0 & x_3^2 & 2x_3y_3 & 3y_3^2 & x_3^2(x_3+2y_3) & y_3(4y_3^2+3x_3y_3+2x_3^2) \\
0 & 0 & 0 & 0 & 1 & 0 & 0 & 2x_3 & 2y_3 & 0 & 3x_3^2+4x_3y_3 & 3y_3^2+4x_3y_3
\end{vmatrix} \tag{6.213}
$$

Fig. 6.25. The four global shape functions of T12P3I(4/3) element: (a) $\Psi_I^{(00)}(\boldsymbol{x})$; (b) $\Psi_I^{(10)}(\boldsymbol{x})$; (c) $\Psi_I^{(01)}(\boldsymbol{x})$; (d) $\Psi_I^{(11)}(\boldsymbol{x})$.

The RKEM global shape functions of the triangle resume the same formula,

$$\Psi_I^{(\alpha)}(\boldsymbol{x}) = \sum_{k=1}^{\ell} \sum_{j \in \Lambda_{e_k}} \left(\mathcal{K}^{\rho}_{e_k,j}(\boldsymbol{x}) \Delta V_{e_k,j} \right) \psi^{(\alpha)}_{e_k,ik}(\boldsymbol{x}) \ . \tag{6.217}$$

6.5.5 2D Example III: Q12P3I1 Quadrilateral Element

One can consider constructing quadrilateral element by using the same technique. To illustrate an example, we outline the procedure to construct a twelve degrees of freedom quadrilateral element, $Q12P3I1$. The element interpolation provided by the global partition polynomials in an element is

$$\begin{aligned} \mathcal{I}_{ele} f &= \sum_{i=1}^{4} \left(\psi^{(0)}_{e,i} f_{e,i} + \psi^{(10)}_{e,i} \frac{\partial f}{\partial x} \Big|_{(e,i)} + \psi^{(01)}_{e,i} \frac{\partial f}{\partial y} \Big|_{(e,i)} \right) \\ &= c_1 + c_2 x + c_3 y + c_4 x^2 + c_5 xy + c_6 y^2 + c_7 x^3 + c_8 x^2 y + c_9 x y^2 \\ &\quad + c_{10} y^3 + c_{11} x^3 (x+y) + c_{12} y^3 (x+y) \end{aligned} \tag{6.218}$$

To link the nodal data with constants,$c's$, vectors, $\boldsymbol{\psi}$, $\mathbf{f}$, $\mathbf{p}$, and $\mathbf{c}$ are defined

Fig. 6.26. Illustration of Q12P3I1 quadrilateral element.

$$\boldsymbol{\psi}_e^T(\boldsymbol{x}) := \{\psi_{e,1}^{(00)}, \psi_{e,1}^{(10)}, \psi_{e,1}^{(01)}, \psi_{e,2}^{(00)}, \psi_{e,2}^{(10)}, \psi_{e,2}^{(01)}, \psi_{e,3}^{(00)}, \psi_{e,3}^{(10)}, \psi_{e,3}^{(01)}, \psi_{e,4}^{(00)}, \psi_{e,4}^{(10)}, \psi_{e,4}^{(01)}\} \tag{6.219}$$

$$\mathbf{f}_e^T := \{f_1, f_{1x}, f_{1y}, f_2, f_{2x}, f_{2y}, f_3, f_{3x}, f_{3y}, f_4, f_{4x}, f_{4y}\}_e \tag{6.220}$$

$$\mathbf{p}^T(\boldsymbol{x}) := \{1, x, y, x^2, xy, y^2, x^3, x^2y, xy^2, y^3, x^3(x+y), y^3(x+y)\} \tag{6.221}$$

$$\mathbf{c}_e^T := \{c_1, c_2, c_3, c_4, c_5, c_6, c_7, c_8, c_9, c_{10}, c_{11}, c_{12}\}_e \tag{6.222}$$

We can write that

$$\mathcal{I}_{loc} f = \boldsymbol{\psi}_e^T \mathbf{f}_e = \mathbf{p}^T \mathbf{c}_e. \tag{6.223}$$

Again, the nodal values are related with coefficients c's by a system of 12

(a) (b) (c)

Fig. 6.27. The shape functions of Q12P3I1 element.

linear algebraic equations

$$\mathbf{f}_e = \mathbf{C}_e \mathbf{c}_e \tag{6.224}$$

where matrix $\mathbf{C}_e$ is defined by Eq. (6.225).

$$\mathbf{C}_e = \begin{vmatrix} 1 & x_1 & y_1 & x_1^2 & x_1y_1 & y_1^2 & x_1^3 & x_1^2y_1 & x_1y_1^2 & y_1^3 & x_1^3(x_1+y_1) & y_1^3(x_1+y_1) \\ 0 & 1 & 0 & 2x_1 & y_1 & 0 & 3x_1^2 & 2x_1y_1 & y_1^2 & 0 & 4x_1^3+3x_1^2y_1 & y_1^3 \\ 0 & 0 & 1 & 0 & x_1 & 2y_1 & 0 & x_1^2 & 2x_1y_1 & 3y_1^2 & x_1^3 & 4y_1^3+3y_1^2x_1 \\ 1 & x_2 & y_2 & x_2^2 & x_2y_2 & y_2^2 & x_2^3 & x_2^2y_2 & x_2y_2^2 & y_2^3 & x_2^3(x_2+y_2) & y_2^3(x_2+y_2) \\ 0 & 1 & 0 & 2x_2 & y_2 & 0 & 3x_2^2 & 2x_2y_2 & y_2^2 & 0 & 4x_2^3+3x_2^2y_2 & y_2^3 \\ 0 & 0 & 1 & 0 & x_2 & 2y_2 & 0 & x_2^2 & 2x_2y_2 & 3y_2^2 & x_2^3 & 4y_2^3+3y_2^2x_2 \\ 1 & x_3 & y_3 & x_3^2 & x_3y_3 & y_3^2 & x_3^3 & x_3^2y_3 & x_3y_3^2 & y_3^3 & x_3^3(x_3+y_3) & y_3^3(x_3+y_3) \\ 0 & 1 & 0 & 2x_3 & y_3 & 0 & 3x_3^2 & 2x_3y_3 & y_3^2 & 0 & 4x_3^3+3x_3^2y_3 & y_3^3 \\ 0 & 0 & 1 & 0 & x_3 & 2y_3 & 0 & x_3^2 & 2x_3y_3 & 3y_3^2 & x_3^3 & 4y_3^3+3y_3^2x_3 \\ 1 & x_4 & y_4 & x_4^2 & x_4y_4 & y_4^2 & x_4^3 & x_4^2y_4 & x_4y_4^2 & y_4^3 & x_4^3(x_4+y_4) & y_4^3(x_4+y_4) \\ 0 & 1 & 0 & 2x_4 & y_4 & 0 & 3x_4^2 & 2x_4y_4 & y_4^2 & 0 & 4x_4^3+3x_4^2y_4 & y_4^3 \\ 0 & 0 & 1 & 0 & x_4 & 2y_4 & 0 & x_4^2 & 2x_4y_4 & 3y_4^2 & x_4^3 & 4y_4^3+3y_4^2x_4 \end{vmatrix} \tag{6.225}$$

By solving the linear algebraic equation, one can then find vector $\mathbf{c}_e$

$$\mathbf{c}_e = \mathbf{C}_e^{-1}\mathbf{f} \tag{6.226}$$

and then the global partition polynomials

$$\boldsymbol{\psi}_e(\boldsymbol{x}) = \mathbf{C}_e^{-T}\mathbf{p}(\boldsymbol{x}) \ . \tag{6.227}$$

6.6 Numerical Examples

To validate the method, the proposed RKEM interpolants are tested in Galerkin procedures to solve various Kirchhoff plate problems, because the Galerkin weak formulation of a Kirchhoff plate involves second derivatives and a global $C^1(\Omega)$ interpolation field is the minimum requirement. Moreover, the boundary conditions of Kirchhoff plate problems involve interpolating boundary data of both the first order derivative (slopes) and the second order derivative (curvatures), it provides a severe test to the newly proposed RKEM triangle interpolants. For more information on how to impose boundary conditions for finite element computation of thin plates, readers are referred to Hughes' finite element book[209] pages 324 - 327.

We consider three problems: (1) a simply supported triangle plate subjected uniform load; (2) a simply supported square plate subjected uniform load; and (3) a clamped circular plate under uniform load.

6.6.1 Equilateral Triangular Plate

To validate the method, an equilateral triangular thin plate under uniform load is solved first by using the proposed method. The coordinate axes are taken as shown in Fig. 6.28(a). In the case of a uniformly loaded plate with simply supported ends, the deflection of surface is given as:[435]

Fig. 6.28. Problem description for plate.

$$w = \frac{p}{64aD}\left[x^3 - 3y^2x - a(x^2+y^2) + \frac{4}{27}a^3\right]\left(\frac{4}{9}a^2 - x^2 - y^2\right) \quad (6.228)$$

where a=1 is the height of the triangular plate.

Three discretizations with 9, 36, and 144 T12P3I3 elements shown in Fig. 6.29 are used for the convergency study. Due to the generalized Kronecker delta property of globally conforming interpolation, it is easy to exactly impose the simply supported boundary conditions at boundary nodes. The maximum deflection at the center for the three cases are, $1.08428070E-03\frac{pa^4}{D}$, $1.03376896E-03\frac{pa^4}{D}$, and $1.02974603E-03\frac{pa^4}{D}$, respectively; and the exactsolution is $1.02880658E-03\frac{pa^4}{D}$. The deflection surfaces corresponding to the three models are shown in Fig. 6.30. The L_2 error norms in the primary variable, and its first and second derivatives are shown in Fig. 6.31 for interpolation and Galerkin solutions, respectively. The convergency rates in terms of error norms L_2, H^1 and H^2 are 3.2, 2.8, and 1.7 for the Galerkin solution, respectively. They match well with the convergency rates for the interpolation solution, which are 3.4, 2.4, and 1.4 in terms of error norms L_2, H^1 and H^2, respectively.

6.6.2 Clamped Circular Plate

We now solve a clamped unit diameter circular Kirchhoff plate, as depicted in Fig. 6.32.

(a) (b)

Fig. 6.32. Problem domain and triangle mesh.

The exact solution is given in[437] for a plate of radius a as

$$w(x,y) = \frac{p}{64D}\left(a^2 - x^2 - y^2\right)^2$$

The deformed shape of the circular plate is juxtaposed with the finite element mesh depicted in Fig. 6.32.

The convergence rates of L_2, H_1 and H_2 error norm are computed and are tabulated in Table 6.2.

Obs.: Utilizar 6.6.2 – Clamped Circuluar Plane – interessante. Adaptar estes cálculus para um curvatura negativa (k).

Interessante:

Fig. 1.2. Voronoi diagram of a set of seven nodes: (a) Delaunay triangulation DT(N), and (b) Natural neighbor circum-circles.

and Delaunay tessellation. For simplicity, we only outline the main properties of the Voronoi diagram and Delaunay tessellation in a two-dimensional Euclidean space $\mathbb{R}^2$, though the theory is, however, applicable in a general d-dimensional framework.

Consider a set of distinct nodes $\Lambda = \{1, 2, \cdots, I, \cdots, NP\}$ in $\mathbb{R}^2$. The Voronoi diagram (or 1st-order Voronoi diagram) of the point set Λ is a subdivision of the plane into regions (tiles) $\mathbb{R}^2 \subset \bigcup_{I \in \Lambda} \{T_I\}$, where each T_I (tile) is either closed and convex (in interior), or unbounded (at boundary). The tile T_I is defined as a region that contains a node n_I, such that any point in T_I is closer to I than to any other nodal point $J \in \Lambda$ $(J \neq I)$,

$$T_I = \left\{ \mathbf{x} \in \mathbb{R}^2 : d(\boldsymbol{x}, \boldsymbol{x}_I) \leq d(\boldsymbol{x}, \boldsymbol{x}_J),\ \forall I, J \in \lambda \right\} \tag{1.72}$$

where $d(\boldsymbol{x}, \boldsymbol{x}_I) := \|\boldsymbol{x} - \boldsymbol{x}_I\|$ is the Euclidean norm.

The Voronoi cell for node A and the Voronoi diagram for a set of seven nodes are shown in Fig. 1.2. In Fig. 1.2, it is shown that each Voronoi cell T_I is the intersection of finitely many open half-spaces, each being delimited by the perpendicular bisector of the line joining nodes I and J $(J \neq I)$. Denote the convex hull, $CH(\Lambda)$, as the smallest convex set containing the NP nodes. For all nodes I that are inside the convex hull, Voronoi cells are closed and convex, while the cells associated with nodes on the boundary of the convex hull are unbounded.

The Delaunay triangulation, which is the straight-line dual of the Voronoi diagram, is constructed by connecting the nodes whose Voronoi cells have common boundaries. The duality between the Voronoi diagram and Delaunay triangulation refers to the fact that there is a Delaunay edge between two nodes in the plane if only their Voronoi cells share a common edge. Among all triangulations, the Delaunay triangulation maximizes the minimum angle in each individual triangle, which is a desired property in finite element tri-

1.2.8 Voronoi Diagram and Delaunay Tessellation

The Voronoi diagram is a fundamental structure in computational geometry, because the Voronoi diagram and its dual Delaunay tessellation are one of the most fundamental and useful topological (geometric) structures that connect a set of randomly distributed particles. Today, some of the best finite element mesh generators, or mesh generation algorithms are based on the Voronoi diagram and Delaunay tessellation. Apparently, some of the mesh-free discretizations are also based on local properties of the Voronoi diagram and Delaunay tessellation. For simplicity, we only outline the main properties of the Voronoi diagram and Delaunay tessellation in a two-dimensional Euclidean space IR2, though the theory is, however, applicable in a general d-dimensional framework.

Consider a set of distinct nodes $\Lambda = \{1, 2, \cdots, I, \cdots, NP\}$ in $\mathbb{R}^2$. The Voronoi diagram (or 1st-order Voronoi diagram) of the point set Λ is a subdivision of the plane into regions (tiles) $\mathbb{R}^2 \subset \bigcup_{I \in \Lambda} \{T_I\}$, where each T_I (tile) is either closed and convex (in interior), or unbounded (at boundary). The tile T_I is defined as a region that contains a node n_I, such that any point in T_I is closer to I than to any other nodal point $J \in \Lambda$ $(J \neq I)$,

$$T_I = \left\{ \mathbf{x} \in \mathbb{R}^2 : d(\boldsymbol{x}, \boldsymbol{x}_I) \leq d(\boldsymbol{x}, \boldsymbol{x}_J),\ \forall I, J \in \lambda \right\} \tag{1.72}$$

where $d(\boldsymbol{x}, \boldsymbol{x}_I) := \|\boldsymbol{x} - \boldsymbol{x}_I\|$ is the Euclidean norm.

Obs.: Estudar a relação do Euclidean Norm em relação à curvatura do espaço.

1.2.4 Hilbert Space

Concepts in linear functional analysis are central to a qualitative understanding of convergence of any numerical method. For the most part, knowledge in elementary functional analysis including Hilbert space and Galerkin variational form of a boundary value problem (BVP) will suffice. In a few cases, we may venture to discuss the results in general Sobolev space (Adams 1975). The notion of function spaces in describing the topological structure of a set of functions in $\mathbb{R}^d$ is analogous to that of vector spaces in linear algebra. The abstract notation, $Au = f$, is used to describe a partial differential equation (PDE). It is noted that the differential operator $A : U \to V$ maps functions from one function space U to another function space V. All the discussions conducted in this book are restricted to real valued functions.

Let Ω be an open bounded domain in $\mathbb{R}^d$ with a piecewise continuous boundary Γ (Γ is a Lipschitz boundary). The function space $L^2(\Omega)$ is defined as

$$L^2(\Omega) := \left\{ f \,\middle|\, \int_\Omega f^2 d\Omega < +\infty \right\} \tag{1.19}$$

the space is equiped with the L^2 norm

$$\|u\|_{L^2(\Omega)} := (u, u)^{1/2}_{L^2(\Omega)} \tag{1.20}$$

where the operator $(,)$ is a scalar product defined as

$$(u, v)_{L^2(\Omega)} := \int_\Omega uv d\Omega, \quad u, v \in L^2(\Omega) \tag{1.21}$$

Multi-index Notation. It is convenient to use multi-index notation to express partial derivatives in multiple dimensions.

Let $\mathbf{Z}^d$ denote the set of all ordered d-tuples of non-negative integers. A multi-index is an ordered collection (d-tuple) of d non-negative integers, $\alpha = (\alpha_1, \cdots, \alpha_d)$, and its length is defined as

$$|\alpha| = \sum_{i=1}^{d} \alpha_i \tag{1.22}$$

We write $\alpha! = \alpha_1!\alpha_2! \cdots \alpha_d!$ and $\varrho^\alpha = \varrho_1^{\alpha_1} \varrho_2^{\alpha_2} \cdots \varrho_d^{\alpha_d}$ and $\mathbf{x}^\alpha = x_1^{\alpha_1} x_2^{\alpha_2} \cdots x_d^{\alpha_d}$. For a differentiable function $u(\mathbf{x})$ and any α with $|\alpha| \le p$,

$$D^\alpha u(\mathbf{x}) = \frac{\partial^{|\alpha|} u(\mathbf{x})}{\partial x_1^{\alpha_1} \cdots \partial x_d^{\alpha_d}} \tag{1.23}$$

is the αth order partial derivative. As usual, $D^0 u(\mathbf{x}) = u(\mathbf{x})$.

Linear Functional. We consider a linear functional $l : V \to \mathbb{R}$ that maps real-valued functions from a Hilbert space V to real numbers in $\mathbb{R}$. The functional l is defined by its action on an arbitrary member $v \in V$ by

$$< l, v >= (u, v)_{L^2(\Omega)} \tag{1.24}$$

for a given u and arbitrary v. The notation $\langle \cdot, \cdot \rangle$ is used to denote the duality pair. The space of bounded linear functionals on V is denoted by the dual space V', and for $l \in V'$ the norm $\|l\|_{V'}$ is defined as

$$\|l\|_{V'} = \sup_{v \in V \ \{0\}} \frac{\langle l, v \rangle}{\|v\|_V} \ . \tag{1.25}$$

The functional l is said to be continuous, if there exists a positive constant M such that

$$|\langle l, v \rangle| \leq M \|v\|_V \ . \tag{1.26}$$

Weak Derivatives. We denote $C_0^\infty(\Omega)$ as the space of infinitely differentiable functions which are non-zero only on a compact subset of Ω.

If $u \in L^2(\Omega)$ is a locally integrable function, we say that u possesses the (weak) derivative $v = D^\alpha u$ in $L^2(\Omega)$, if and only if $v \in L^2(\Omega)$ and

$$\langle v, w \rangle = (-1)^{|\alpha|} \langle u, D^\alpha w \rangle, \ \ \forall \ w \in C_0^\infty(\Omega) \ . \tag{1.27}$$

Introduce Hilbert space $H^m(\Omega)$. The function space, $H^m(\Omega)$, is defined as the space consisting of those functions in $L^2(\Omega)$ that have their weak partial derivatives exist up to order m, i.e.

$$H^m(\Omega) = \{u \ \Big| \ D^\alpha u \in L^2(\Omega), \ \ \forall \ |\alpha| \leq m\} \tag{1.28}$$

$H^m(\Omega)$ is a Hilbert space, because its norm is induced by the following inner product

$$\|u\|_{H^m(\Omega)} := (u, u)^{1/2}_{H^m(\Omega)} \tag{1.29}$$

where the inner product

$$(u, v)_{H^m(\Omega)} = \sum_{|\alpha| \leq m} (D^\alpha u, D^\alpha v)_{L^2(\Omega)} \ , \quad \forall \ u, v \in H^m(\Omega) \ . \tag{1.30}$$

We note that $H^0(\Omega) = L^2(\Omega)$ and the family of semi-norm on $H^m(\Omega)$ are defined as

$$|u|_{H^p(\Omega)} := \left\{ \sum_{|\alpha| = p} (D^\alpha u, D^\alpha u)_{L^2(\Omega)} \right\}^{1/2} \tag{1.31}$$

where $1 \leq p \leq m$. We denote function space $H_0^m(\Omega)$ as a subspace of $H^m(\Omega)$ in which all the functions are compactly supported in a subset of Ω. For example,

$$H_0^1(\Omega) = \left\{ u \;\middle|\; u \in H^1(\Omega), u\,|_{\boldsymbol{x}\in\Gamma} = 0 \right\} \tag{1.32}$$

$$H_0^2(\Omega) = \left\{ u \;\middle|\; u \in H^1(\Omega), u\,|_{\boldsymbol{x}\in\Gamma} = 0, \;\; \frac{\partial u}{\partial n}\,|_{\boldsymbol{x}\in\Gamma} = 0 \right\} \tag{1.33}$$

where n is the outward normal of Γ.

1.2.5 Variational Weak Formulation

Before discussing the variational formulation, a few definitions are in order. $a(u,v) : H \times H \to \mathbb{R}$ that maps a pair of functions from a Hilbert space to real number in $\mathbb{R}$. Since the operator $a(\,\cdot\,,\,\cdot\,)$ is linear in both slots, it is termed as bilinear form.

Definition 1.2.3 (Continuity). *Let V be a Hilbert space. A bilinear form $a(u,v) : V \times V \to \mathbb{R}$ is continuous if there exists a constant $K > 0$ such that*

$$|a(u,v)| \leq K\|u\|_V\|v\|_V, \quad \forall\, u,v \in V \tag{1.34}$$

Definition 1.2.4 (Ellipticity). *Let V be a Hilbert space. A continuous bilinear form is said to be V-elliptic, or coercive, if there exists a constant $\alpha > 0$ such that*

$$a(v,v) \geq \alpha\|v\|^2\,, \quad \forall\, v \in V \tag{1.35}$$

Consider a Hilbert space H and let U and V be convex subspaces of H. Let $a(u,v) : U \times V \to \mathbb{R}$ be a continuous, symmetric, V-elliptic bilinear form and let $l : V \to \mathbb{R}$ be a continuous linear functional on V. We consider the following abstract variational formulation,

$$a(u,v) = \langle l, v\rangle, \quad \forall\, v \in V \tag{1.36}$$

where any function $u \in U$ is usually called a trial function, and functions $v \in V$ are called test functions.

From a physical viewpoint, the above variational statement is equivalent to the following minimization problem

$$\inf_{u\in U} J(u) = \inf_{u\in U} \frac{1}{2}a(u,u) - \langle l, u\rangle \tag{1.37}$$

To illustrate how to formulate a Galerkin variational weak form we consider the following Dirichlet boundary value problem,

$$-\nabla^2 u + u = f, \quad \forall\, \boldsymbol{x} \in \Omega \tag{1.38}$$

$$u = 0, \quad \forall\, \boldsymbol{x} \in \Gamma \tag{1.39}$$

Definition 1.2.3 (Continuity). Let V be a Hilbert space. A bilinear form a(u, v) : V × V → IR is continuous if there exists a constant K > 0 such that

$$|a(u,v)| \leq K\|u\|_V\|v\|_V, \quad \forall\, u,v \in V$$

Estudar:

Definition 1.2.4 (Ellipticity). *Let V be a Hilbert space. A continuous bilinear form is said to be V-elliptic, or coercive, if there exists a constant $\alpha > 0$ such that*

$$a(v, v) \geq \alpha \|v\|^2 \ , \quad \forall\, v \in V \tag{1.35}$$

Consider a Hilbert space H and let U and V be convex subspaces of H. Let $a(u, v) : U \times V \to \mathbb{R}$ be a continuous, symmetric, V-elliptic bilinear form and let $l : V \to \mathbb{R}$ be a continuous linear functional on V. We consider the following abstract variational formulation,

$$a(u, v) = \langle l, v \rangle, \quad \forall\, v \in V \tag{1.36}$$

where any function $u \in U$ is usually called a trial function, and functions $v \in V$ are called test functions.

From a physical viewpoint, the above variational statement is equivalent to the following minimization problem

$$\inf_{u \in U} J(u) = \inf_{u \in U} \frac{1}{2} a(u, u) - \langle l, u \rangle \tag{1.37}$$

To illustrate how to formulate a Galerkin variational weak form we consider the following Dirichlet boundary value problem,

$$-\nabla^2 u + u = f, \quad \forall\, \boldsymbol{x} \in \Omega \tag{1.38}$$

$$u = 0, \quad \forall\, \boldsymbol{x} \in \Gamma \tag{1.39}$$

Obs.: Estudar estes aspectos na projeção dupla elíptica. Interessante !!! Ficar atento aos cálculos e as checagens (Voronoi diagram).

Choose $V = H_0^1(\Omega)$. Multiplying Eq. (1.38) by an arbitrary function $v \in V$ and integrating them over Ω, one may obtain that

$$\int_\Omega \Big(-\nabla^2 u + u\Big) v d\Omega = \int_\Omega f v d\Omega \tag{1.40}$$

Integration by parts yields

$$\int_\Omega v \nabla^2 u d\Omega = -\int_\Omega \nabla u \cdot \nabla v d\Omega + \int_\Gamma v \frac{\partial u}{\partial n} d\Gamma \tag{1.41}$$

where n is the outward normal of Γ. Considering the boundary condition (1.39), one may derive

$$\int_\Omega \Big(\nabla u \cdot \nabla v + uv\Big) d\Omega = \int_\Omega f v d\Omega \tag{1.42}$$

which is the variational weak form of (1.38)–(1.39).

Comparing Eq. (1.42) with the abstract variational form (1.36), one can identify that

$$a(u, v) = \int_\Omega (\nabla u \cdot \nabla v + uv) d\Omega \tag{1.43}$$

$$\langle l, v \rangle = \int_\Omega f v d\Omega \tag{1.44}$$

In this case, $a(u, u) = \|u\|^2_{H^1(\Omega)}$. It is obvious that the bilinear form is continuous, symmetric, and coercive. Since the solution of Eq. (1.42) belongs $H^1(\Omega)$ while the solution of Eqs. (1.38) – (1.39) belong at least to $C_0^1(\Omega)$, the solution of (1.42) is referred to as *weak solution*, because it has a lesser requirement on the solution's differentiability.

1.2.6 Galerkin Methods

In the Galerkin variational statement (1.36), both function spaces, U and V are infinite dimensional subspaces of a Hilbert space H. In computational practice, an approximated solution is sought in a finite dimensional subspace of U, which is built on discretization of the continuum. Let $U^h \subset U$ and $V^h \subset V$. They are both spanned by a set of shape functions, i.e.

$$U^\varrho = span\{\Psi_I\}_{I \in \Lambda} \tag{1.45}$$

$$V^\varrho = span\{\Phi_I\}_{I \in \Lambda} \tag{1.46}$$

where parameter ϱ refers to a measure that is related to spacing of the discretization. In the context of finite element methods, we usually label $\varrho = h$, and the Galerkin variational statement becomes:

Find $u^h \in U^h$ such that

$$a(u^h, v^h) =< l, v^h >, \quad \forall\, v^h \in V^h \tag{1.47}$$

If the trial and test functions spaces are identical, $U^h \equiv V^h$, the Galerkin method is called Ritz-Galerkin method, or Bubnov-Galerkin method. On the other hand, if the trial and test function spaces are different, $U^h \neq V^h$, the associated Galerkin method is called Petrov-Galerkin method, in which the trial function and test function belong to different function spaces.

Consider a Bubnov-Galerkin formulation, $U^h = V^h$. Both the trial function and the test function can be expressed by the same interpolant

$$u^h(\boldsymbol{x}) = \sum_{I \in A} \Phi_I(\boldsymbol{x}) u_I \tag{1.48}$$

$$v^h(\boldsymbol{x}) = \sum_{I \in A} \Phi_I(\boldsymbol{x}) v_I \tag{1.49}$$

Substituting (1.48) and (1.49) into (1.47) yields a system of algebraic equations

$$\sum_{I \in A} \sum_{J \in A} a(\Phi_I, \Phi_J) u_I v_J = \sum_{J \in A} < l, \Phi_J > v_J, \quad \forall\, v_J \in V^h \tag{1.50}$$

which can be recast into the form

$$\sum_{J \in A} v_J \Big(\sum_{I \in A} K_{IJ} u_I - f_J \Big) = 0 \tag{1.51}$$

where $K_{IJ} = a(\Phi_I, \Phi_J)$ and $f_J =< l, \Phi_J >$. Since $v_J \in V^h$ is arbitrary, the following finite dimension linear algebraic equations can be obtained,

$$[K_{IJ}][u_J] = [f_I] \tag{1.52}$$

where $[K_{IJ}]$ is referred to as the stiffness matrix because of its early application in structural mechanics.[433]

1.2.7 Time-stepping Algorithms

The time integration algorithm is a critical part of meshfree particle methods. It is a challenge today to integrate a multiple time scale system with accuracy, which occurs in many particle method based simulations. To be self-sufficient, the conventional time-stepping algorithms are listed as follows. Special issues on time integration relating to specific particle methods will be treated separately in related chapters.

To outline time-stepping algorithms, we consider the following semi-discrete equation of motion, which may be formed by any spatial discretization process,

$$\mathbf{M}\ddot{\mathbf{d}} + \mathbf{C}\dot{\mathbf{d}} + \mathbf{K}\mathbf{d} = \mathbf{F} \tag{1.53}$$

1 Calculus in curved space

In this chapter I attempt to motivate and explain the main ideas and suggest images that illustrate the mathematical apparatus of differential geometry. The actual explanations start in Sec. 1.2.2. Additional literature on differential geometry from a mathematical viewpoint is [22, 11]. A more modern mathematical textbook (which I did not read) is [17].

1.1 Summary

General Relativity (**GR**) is a currently well-established physical theory of gravitation whose mathematical apparatus is based on differential geometry (more specifically, tensor calculus in curved spaces). In this chapter, I introduce the main concepts of this calculus: manifolds, tangent spaces, covariant derivatives, and curvature. I will explain and use the index-free notation. You (the reader) will perhaps appreciate this material more fully if you are already somewhat familiar with tensor calculus and GR, at least to the extent covered in Appendix A.

The pragmatic side of this chapter is to develop sufficiently powerful formalism for index-free calculations, which will be heavily used throughout this book. You may skip this chapter on first reading iff[1] you are familiar with the following concepts and notations.

$\mathcal{M}$	smooth manifold
$\mathbb{R}^n$	n-dimensional Euclidean space
$T_p\mathcal{M}, T_p^*\mathcal{M}$	(co)tangent spaces to $\mathcal{M}$ at point p
$T\mathcal{M}$	tangent bundle of a manifold $\mathcal{M}$
$\mathbf{v} \in T_p\mathcal{M}$	tangent vector at point p
$\mathbf{v} \circ f$	derivative of function f w.r.t. vector field $\mathbf{v}$
∂_t	vector field along a coordinate axis t
$[\mathbf{a}, \mathbf{b}] \equiv \mathcal{L}_{\mathbf{a}}\mathbf{b}$	commutator of two vector fields
$\mathcal{L}_{\mathbf{v}}T$	Lie derivative of tensor T w.r.t. vector $\mathbf{v}$
$\mathbf{u} \otimes \mathbf{v}$	tensor product of vectors
$\omega \circ \mathbf{v}$	1-form ω applied to vector $\mathbf{v}$
$\int \omega, \mathrm{d}\omega$	integral / exterior differential of n-form ω
$\omega_1 \wedge \omega_2$	exterior product of n-forms ω_1 and ω_2
$\iota_{\mathbf{v}}\omega$	insertion of vector $\mathbf{v}$ into n-form ω
$g(\mathbf{a}, \mathbf{b})$	scalar product of vectors using a metric g
$\tilde{g}\mathbf{v}$	1-form corresp. to vector $\mathbf{v}$ through metric g
$\tilde{g}^{-1}\omega$	vector corresp. to 1-form ω through metric g
$\boldsymbol{\varepsilon}$	volume n-form, Levi-Civita tensor
$\nabla_{\mathbf{a}}\mathbf{b}$	covariant derivative of vector $\mathbf{b}$ w.r.t. vector $\mathbf{a}$
$\mathrm{div}\mathbf{u}$	divergence of vector field $\mathbf{u}$
$R(\mathbf{a}, \mathbf{b})\mathbf{c}$	curvature tensor (Riemann tensor)
$R(\mathbf{a}, \mathbf{b}, \mathbf{c}, \mathbf{d})$	"fully covariant" Riemann tensor
$\mathrm{Ric}(\mathbf{a}, \mathbf{b})$	Ricci tensor

Concepts covered in this chapter also include: connecting vector fields; definition of the metric-compatible (Levi-Civita) connection on a manifold with a metric; torsion and torsion-freeness; properties of the Riemann tensor; geodesics and geodesic deviation; Riemann tensor for manifolds of constant curvature.

[1] If and only if.

1.1.1 Index-free notation

One approach to differential geometry is to treat vectors and tensors as multi-indexed arrays of numbers (called **components**), such as $T_{\mu\nu}$ or $R^{\lambda}{}_{\mu\alpha\beta}$, which depend on the choice of the coordinate system $\{x^\mu\}$. One manipulates expressions with many indices, such as $g^{\mu\alpha}g_{\lambda\mu,\nu}g^{\nu\beta}$, and checks at the end of the calculations that the results are **covariant** (i.e. transform correctly under changes of coordinates). This approach was pioneered by Einstein and is still the way tensor calculus is presented in the current physical literature. I assume that you were already exposed to an introductory course of GR formulated using coordinates and components. If you are not sure, please scan Sec. A.2–A.7 in Appendix A for unfamiliar equations.

In the mathematical literature, the coordinate-free approach and the **index-free notation** are predominant. For example, the scalar product of vectors is denoted by $g(\mathbf{a}, \mathbf{b})$ or just $\langle \mathbf{a}, \mathbf{b} \rangle$ instead of $g_{\mu\nu}a^\mu b^\nu$ or $a_\mu b^\mu$. The preference for the coordinate-free approach is, in my opinion, due to the different character of the tasks typically undertaken by mathematicians and by physicists. Mathematicians study abstract relationships between objects and are more interested in finding objects that have rich properties and whose interconnections explain earlier results on a more general level and yield new concepts. On the other hand, physicists are mostly interested in making specific computations and deriving equations that will eventually give numerical values for quantities, even if the methods of computation are not particularly general, elegant, or illuminating.

In the coordinate-free approach, one avoids introducing a particular coordinate system $\{x^\mu\}$, and one does not talk about components of tensors. Instead, one uses geometrically defined operations (such as, the covariant derivative or the Lie derivative) and the algebraic properties of tensors. In a calculation where a particular tensor is sought, especially when no symmetries are present, it may be helpful to introduce a suitable coordinate system and to determine the components of that tensor. However, often one needs to perform a "general" calculation that does not depend on a particular tensor (e.g., an investigation of a general property of the curvature tensor). In most cases, such "general" calculations are easier to perform in the coordinate-free approach because coordinate systems and components offer no computational or conceptual advantages. The experience of writing this book shows that the coordinate-free approach is well suited for applications such as singularity theorems or the Hamiltonian formulation of GR.

It is natural[2] to use the index-free notation when one adopts the coordinate-free approach. Here is an example of a calculation in the index-free notation. *Statement*: If a vector $\mathbf{u}$ is geodesic then $g(\mathbf{u}, \mathbf{u})$ is constant along the flow lines of $\mathbf{u}$.

[2] Although, strictly speaking, not necessary. Instead, one could use Penrose's "abstract index notation," where a^μ means a vector with an abstract label μ, rather than an array of components. See Sec. 1.7.1 for more details. One book that consistently uses the coordinate-free approach together with the abstract index notation is [19].

Proof: The derivative of $g(\mathbf{u},\mathbf{u})$ along the flow of $\mathbf{u}$ is

$$\mathcal{L}_{\mathbf{u}} g(\mathbf{u},\mathbf{u}) = \nabla_{\mathbf{u}} g(\mathbf{u},\mathbf{u}) = 2g(\nabla_{\mathbf{u}}\mathbf{u},\mathbf{u}) = 0$$

since $\nabla_{\mathbf{u}}\mathbf{u} = 0$ for geodesic vector fields. For comparison, the same calculation in the index notation looks like this:

$$\frac{d}{d\tau}\left(g_{\mu\nu}u^\mu u^\nu\right) = u^\lambda\left(g_{\mu\nu}u^\mu u^\nu\right)_{;\lambda} = 2g_{\mu\nu}u^\lambda u^\mu{}_{;\lambda}u^\nu = 0$$

since $u^\lambda u^\mu{}_{;\lambda} = 0$.

The index notation is frequently very useful and even unavoidable in some calculations, especially when one needs to manipulate traces of high-rank tensors, as if often the case in GR. Nevertheless, the index-free notation has, in my view, significant advantages in the study of more mathematically advanced topics of field theory and GR. The index-free notation is concise, emphasizes the geometrical meaning of every quantity, and completely excludes non-tensorial quantities from consideration; for instance, the non-tensorial Christoffel symbols cannot even be defined. The index-free approach is well-suited for studying the general properties of various geometrical objects used in GR. Many general derivations (such as computing the second variation of the geodesic length) can be performed faster and more transparently in the index-free notation.

In this text, I adopt the coordinate-free approach; this leaves the choice of an index-free notation or the abstract index notation. I employ index-free calculations when it is practically more convenient than the abstract index notation. The index-free approach turns out to be almost always more convenient, except for certain cases, such as the variation of the Einstein-Hilbert action with respect to the metric, where index-free calculations become cumbersome (although still possible). In those cases I use the abstract index notation. Section 1.7 presents more discussion and shows how to convert expressions between the index-free and the index notations. In this book, I also introduce an admittedly nonstandard but unambiguous and adequate index-free notation for the trace of a tensor (Sec. 1.7.3).

To make the transition to the index-free approach easier for readers accustomed to the index notation, I will sometimes mention the index representation of tensor quantities used throughout the text. The formal correspondence between the index-free and the index notations is summarized in the following table.

$\mathbf{v}$	$v^\alpha\partial_\alpha \equiv v^\alpha\frac{\partial}{\partial x^\alpha}$	ω	$\omega_\alpha \mathrm{d}x^\alpha$
$\mathbf{v}\circ f$	$v^\alpha\partial_\alpha f \equiv v^\alpha f_{,\alpha}$	$\omega\circ\mathbf{v}$	$\omega_\alpha v^\alpha$
$[\mathbf{a},\mathbf{b}]$	$a^\mu\partial_\mu b^\nu - b^\mu\partial_\mu a^\nu$	$\mathbf{d}\omega$	$(\omega_{\alpha,\beta}-\omega_{\beta,\alpha})\,\mathrm{d}x^\alpha\mathrm{d}x^\beta$
$\nabla_{\mathbf{a}}\mathbf{b}$	$a^\nu\nabla_\nu b^\mu \equiv a^\nu b^\mu{}_{;\nu}$	$g(\mathbf{a},\mathbf{b})$	$g_{\mu\nu}a^\mu b^\nu \equiv a_\mu b^\mu$
$\operatorname{div}\mathbf{u}$	$\nabla_\alpha u^\alpha \equiv u^\alpha{}_{;\alpha}$	$\hat{g}\mathbf{v}$	$g_{\alpha\beta}v^\beta \equiv v_\alpha$
$\mathbf{u}\otimes\mathbf{v}$	$u^\alpha v^\beta$	$\hat{g}^{-1}\omega$	$g^{\alpha\beta}\omega_\beta \equiv \omega^\alpha$

Remark on the roman "d": Recently, certain science publishers started enforcing the rule of using a roman "d" (for instance, writing $\mathrm{d}^2x(\tau)/\mathrm{d}\tau^2$ or $\int \mathrm{d}^3x$) rather than an italic "d," as was the common practice during the previous two centuries. I decided that in the present text, the roman symbol "d" will be used to denote the exterior differential in the calculus of differential forms, while the italic "d" will appear in other situations when the traditional usage involves an "infinitesimally small" quantity. My intention is to use a roman "d" for rigorously defined objects, such as differential forms $\mathrm{d}x$, and to contrast them with "infinitesimals" dx, which are only heuristic tools that help the intuition. I write integrals, e.g. $\int \mathrm{d}^3x$, with a roman "d" when the integration of a differential form is implied (note that d^3x is a shorthand notation for a 3-form $\mathrm{d}x\wedge\mathrm{d}y\wedge\mathrm{d}z$). However, I write an italic "d" in integrals where a simple one-dimensional integration $\int f(x)dx$ is actually used. I also write the "metric interval,"

$$ds^2 = dt^2 - dx^2 - dy^2 - dz^2,$$

with an italic "d" because this notation is essentially a jargon that bears only marginally on the calculus of differential forms; for instance, "ds" cannot be understood as a 1-form in this notation.

When using ordinary derivatives, I write $d/d\tau$ and $d^2/d\tau^2$ using the italic d, for the following reasons. The operators $d/d\tau$ and $d^2/d\tau^2$ are not essentially different from the partial derivative operators $\partial/\partial x$ or $\partial^2/\partial x^2$. Traditionally, one writes $\partial f/\partial x$ when f depends not only on x but also on other variables $y, z, \ldots$ that are held constant while $f(x,y,z,\ldots)$ is differentiated with respect to x. On the other hand, one writes df/dx to emphasize that $f(x)$ is a function of only one variable x, or that f is an expression that must be reduced, through suitable substitutions, to a function of x only. This notation is widely used to avoid cluttering the equations with explicit substitutions. For instance, the Euler-Lagrange equation of mechanics is written as

$$\frac{\partial L}{\partial x} - \frac{d}{dt}\frac{\partial L}{\partial \dot{x}} = 0,$$

implying that $\partial L/\partial\dot{x}$ must be expressed as a function of t before evaluating d/dt. However, the differential operators $\partial/\partial x$ and d/dx are not related to the exterior differential d. For this reason, I find it confusing to write "$\mathrm{d}/\mathrm{d}x$" with a roman "d" when "d" means the exterior differential. So I use an italic "d" in "d/dx."

A related recent trend is to write a roman "e" for the base of the natural logarithm and a roman "i" for the imaginary unit ($\mathrm{i}^2 = -1$). The reason for switching to roman"d"s, "e"s, and "i"s is to avoid confusion when other quantities are denoted by the letters d, e, i. In this book, my intention is to make the notation unambiguous. I use a roman "i" for the imaginary unit because the letter i is frequently used as an index, e.g. x_i. However, I use an italic $e = 2.718\ldots$ to avoid confusion with a boldface roman $\mathbf{e}$ frequently used for basis vectors $\{\mathbf{e}_\alpha\}$. ■

1.1.2 Sample practice problems

You should be able to solve these problems if you know the material of Chapter 1.

Null vectors. Prove that two non-parallel null vectors $\mathbf{l},\mathbf{n}$ cannot be orthogonal. In other words, $g(\mathbf{l},\mathbf{n}) = 0$ is equivalent to $\mathbf{l} = \lambda\mathbf{n}$ when $g(\mathbf{l},\mathbf{l}) = g(\mathbf{n},\mathbf{n}) = 0$. Here g is a metric in four-dimensional space with the Lorentzian signature $(+,-,-,-)$.

Extremum of a functional on curves. Consider a functional

$$F[\gamma] = \int_{x_1}^{x_2} f(g(\dot{\gamma},\dot{\gamma}))\mathrm{d}\tau,$$

where $f(x)$ is a given smooth, nonconstant function and $\dot{\gamma}$ is the tangent vector to the curve $\gamma(\tau)$. Derive the Euler-Lagrange equations describing the extremum of the functional $F[\gamma]$.

Symmetric geodesics. Consider a local coordinate system $\{x, y, z\}$ in a three-dimensional space. Suppose that the metric g has the form

$$g = \phi(x)dx^2 + A(y,z)dy^2 + C(y,z)dz^2,$$

where $\phi(x) > 0$, $A(y,z) > 0$, $C(y,z) > 0$ are smooth functions that depend on x, y, z as indicated. Show that lines $y =$ const, $z =$ const (i.e. the coordinate lines of x) are geodesics. Obtain an explicit formula for a Killing vector $\mathbf{k}$ that the metric g admits. Is the vector field $\mathbf{k}$ geodesic?

Extrinsic curvature. A hypersurface with normal vector field $\mathbf{n}$ is embedded in a curved space with metric g. The extrinsic curvature $K(\mathbf{x}, \mathbf{y})$ of the hypersurface is defined as a bilinear form

$$K(\mathbf{x}, \mathbf{y}) = h(\nabla_{\mathbf{x}}\mathbf{n}, \mathbf{y}),$$

where h is the induced metric on the hypersurface and $\mathbf{x}, \mathbf{y}$ are arbitrary vectors tangent to the hypersurface. Starting from the definition and using $g(\mathbf{n}, \mathbf{n}) = 1$, show that $K(\mathbf{x}, \mathbf{y})$ is symmetric, $K(\mathbf{x}, \mathbf{y}) = K(\mathbf{y}, \mathbf{x})$. Compute the extrinsic curvature tensor explicitly for the surface $x^2 + y^2 - z^2 = -1$ defined in 3-dimensional Euclidean space with Cartesian coordinates $\{x, y, z\}$ at the point $\{0, 0, 1\}$, using $\{x, y\}$ as the local coordinates on the surface. ■

1.2 Basic notions: Manifolds and vector fields

In nongravitational physics, one describes events in four-dimensional Minkowski spacetime $\mathbb{R}^4$ with familiar coordinates $\{t, x, y, z\}$. Physical laws are expressed as partial differential equations for various fields in spacetime. General Relativity replaces Minkowski spacetime by a *curved* spacetime, and partial derivatives with respect to $\{t, x, y, z\}$ are replaced by more complicated differential operations. The mathematical concept of a "manifold" and accompanying notions are used to formalize the idea of a "curved space" and the ways of writing differential equations for fields in such spaces.

In the following subsection 1.2.1, I will list concise definitions of manifolds, tangent spaces, vector fields, etc. If you are satisfied by or already familiar with these definitions, you may skip the entire Sec. 1.2 and continue reading from Sec. 1.3. Otherwise, you may find it helpful to read the following sections (from Sec. 1.2.2 onwards) where I explain those definitions more visually.

1.2.1 Definitions

This section concisely summarizes the definitions and properties of manifolds and tangent vectors. If you prefer visual explanations to formal definitions, you may ignore this section and start reading from Sec. 1.2.2.

A **manifold** $\mathcal{M}$ is a set of points (which I informally call a "space") that locally looks like a subset of $\mathbb{R}^n$. In other words, every point $p \in \mathcal{M}$ has a small neighborhood around it, which is one-to-one mapped into a subset of $\mathbb{R}^n$. This mapping is called a **chart** and is equivalent to specifying a set of scalar functions, $x^\mu(p)$, defined in an open neighborhood $\mathcal{U}(p_0)$ of some point p_0 and giving the point $x^\mu \in \mathbb{R}^n$ corresponding to points $p \in \mathcal{M}$. These functions must uniquely identify each point p, so that for any two points p, p' from the neighborhood $\mathcal{U}(p_0)$ we have $x^\mu(p) = x^\mu(p')$ iff $p = p'$. Also, the image of the neighborhood $\mathcal{U}(p_0)$ under the map $p \mapsto x^\mu(p) \in \mathbb{R}^n$ must be an open set in $\mathbb{R}^n$. Under these conditions, the functions $x^\mu(p)$ constitute a **local coordinate system** defined on an open subdomain $\mathcal{U}(p_0) \subset \mathcal{M}$. Of course, different subdomains $\mathcal{U}(p_0)$, $\mathcal{U}(p_1)$, etc., may have different local coordinate systems. Whenever there is an intersection of two domains of $\mathcal{M}$ where local coordinate systems are defined, we get a **coordinate change** map $\mathbb{R}^n \to \mathcal{M} \to \mathbb{R}^n$ defined in a subset of $\mathbb{R}^n$. A manifold is **smooth (differentiable)** if all these coordinate change maps are smooth (differentiable) in the ordinary sense (as functions $\mathbb{R}^n \to \mathbb{R}^n$).

A particular manifold may be specified either by an explicit embedding into a larger space, or by giving a complete set of charts and re-charting maps, specifying how the charts are to be glued together.

A typical example of a manifold is the surface of a sphere in 3-dimensional space, usually called the **two-dimensional sphere** (or **2-sphere**) and denoted S^2. The 2-sphere S^2 is locally like $\mathbb{R}^2$, but globally is not (see Statement 1.2.2.1). It is useful to visualize a manifold as a "surface" embedded in a larger space, and to think that "we" are "flat" observers living entirely within the surface. So "we" cannot see the larger space and must describe the "surface" exclusively through its intrinsic properties.

As an example of a manifold described in a different way, consider the set of all 2×2 unitary complex matrices with unit determinant. These matrices form a group denoted $SU(2)$. (A matrix A is **unitary** if $A^\dagger A = 1$, where $A^\dagger$ is the Hermitian conjugate, i.e. the transposed and complex conjugate matrix.) It is perhaps not immediately clear how to introduce coordinates in this set of matrices. It can be shown (see Statement 7.1.1.2 on page 143) that all matrices $A \in SU(2)$ can be described explicitly as

$$A = \begin{pmatrix} a_0 - \mathrm{i}a_3 & -\mathrm{i}a_1 - a_2 \\ -\mathrm{i}a_1 + a_2 & a_0 + \mathrm{i}a_3 \end{pmatrix},$$

where a_0, ..., a_3 are real numbers satisfying $\sum_{j=0}^{3} a_j^2 = 1$. Therefore, $SU(2)$ is equivalent (as a manifold) to a three-dimensional sphere S^3.

A smooth, one-to-one map from one manifold to another is called a **diffeomorphism**. Two manifolds are called **diffeomorphic** if there exists a diffeomorphism between them. Diffeomorphic manifolds are "topologically equivalent." For example, a sphere can be diffeomorphically mapped onto the surface of a cube, but not onto a torus. Another example we have just seen is an explicit diffeomorphism (specified using coordinates) between $SU(2)$ and S^3.

We will always consider *smooth* finite-dimensional manifolds $\mathcal{M}$ and smooth functions $f(p)$, $p \in \mathcal{M}$, on these manifolds; so we omit the word "smooth" everywhere.

In our notation, $p \in \mathcal{M}$ is a point on a manifold, **scalar functions** (scalar fields) are functions $f : \mathcal{M} \to \mathbb{R}$, so that $f(p)$ is a number, and boldface letters $\mathbf{v}, \mathbf{w}, \ldots$ are vectors and vector fields (defined below). We use Greek letters $\alpha, \beta, \ldots, \lambda, \mu, \ldots$ for tensor indices and also for numbers (scalars).

A **curve** on a manifold is a set of points $\gamma(\tau)$ parametrized by a real number τ, i.e. a smooth map $\gamma : \mathbb{R} \to \mathcal{M}$, sometimes defined only on a subset of $\mathbb{R}$.

A **derivation** D **at a point** $p \in \mathcal{M}$ is a map from scalar func-

tions to numbers, satisfying the "derivative-like" properties

$$\begin{aligned} \mathrm{D}(f+g) &= \mathrm{D}f + \mathrm{D}g, \text{ [linearity]} \\ \mathrm{D}(fg) &= \mathrm{D}(f)g + f\mathrm{D}(g), \text{ [Leibnitz rule]} \\ \mathrm{D}f &= 0 \text{ if } f = \text{const around } p. \end{aligned}$$

All the derivations at a point p form a vector space called the **tangent space** $T_p\mathcal{M}$ at the point p. Vectors from the tangent space are denoted by boldface letters, e.g. $\mathbf{u} \in T_p\mathcal{M}$, and their action on functions is denoted by $\mathbf{u} \circ f$. The number $\mathbf{u} \circ f$ is interpreted as the derivative of the function f at the point p in the direction $\mathbf{u}$. Using a local coordinate system $\{x^\alpha\}$, $\alpha = 1, ..., n$, one can prove that the tangent space is an n-dimensional vector space. An explicit basis in this space is given by the n coordinate derivatives $\mathbf{e}_\alpha \equiv \partial/\partial x^\alpha$. The components of a vector $\mathbf{v}$ in this basis can be found as $v^\alpha = \mathbf{v} \circ x^\alpha$, and then the vector $\mathbf{v}$ is decomposed as

$$\mathbf{v} = \sum_{\alpha=1}^{n} v^\alpha \mathbf{e}_\alpha = \sum_{\alpha=1}^{n} v^\alpha \frac{\partial}{\partial x^\alpha}.$$

The union of all tangent spaces $T_p\mathcal{M}$ for every $p \in \mathcal{M}$ is called the **tangent bundle** of $\mathcal{M}$ and is denoted $T\mathcal{M}$. The tangent bundle is itself a manifold with the same charts as $\mathcal{M}$ but with twice the dimension of $\mathcal{M}$. This is so because every chart will map a patch of $\mathcal{M}$ into a patch of $\mathbb{R}^n$ and tangent vectors map into vectors in $\mathbb{R}^n$, thus the patch of the tangent bundle will map into a patch of $\mathbb{R}^n \times \mathbb{R}^n$.

A **vector field** $\mathbf{v}(p)$ on a manifold $\mathcal{M}$ is a tangent vector $\mathbf{v} \in T_p\mathcal{M}$ chosen at every point $p \in \mathcal{M}$, i.e. a map $\mathbf{v} : \mathcal{M} \to T\mathcal{M}$ such that the image $\mathbf{v}(p)$ of every point p belongs to the tangent space $T_p\mathcal{M}$ at the same point p.

A **covector** is a linear map ω from vectors $\mathbf{v}$ into numbers. The space of covectors to tangent vectors at a point p is denoted by $T_p^*\mathcal{M}$ and is called the **cotangent space** at point p. A covector $\omega(p) \in T_p^*\mathcal{M}$ chosen at every point $p \in \mathcal{M}$ is called a **1-form**. The pointwise action of a 1-form ω on a vector field $\mathbf{v}$ is denoted by $\omega \circ \mathbf{v}$ and is a scalar function on $\mathcal{M}$. A **tensor field** on a manifold is defined similarly: it is a tensor based on the tangent space at a point p.

The **commutator** of vector fields $\mathbf{u}$ and $\mathbf{v}$ is the vector field $[\mathbf{u}, \mathbf{v}]$ defined by its action on functions f by

$$[\mathbf{u}, \mathbf{v}] \circ f \equiv \mathbf{u} \circ (\mathbf{v} \circ f) - \mathbf{v} \circ (\mathbf{u} \circ f).$$

(It can be shown that $[\mathbf{u}, \mathbf{v}]$ also satisfies the properties of a vector field; see Statement 1.2.10.1.) One says that the vector fields **commute** if their commutator is equal to zero. For example, coordinate basis vector fields ∂_x and ∂_y commute because $\partial_x\partial_y f = \partial_y\partial_x f$ for smooth functions $f(x, y)$. On the other hand, vector fields $x\partial_y$ and ∂_x do not commute because

$$x\partial_y(\partial_x f) - \partial_x(x\partial_y f) = -\partial_y f \neq 0.$$

A vector field $\mathbf{c}$ is called a **connecting vector** for the vector field $\mathbf{v}$ if $[\mathbf{c}, \mathbf{v}] = 0$. (Since $[\mathbf{c}, \mathbf{v}] = -[\mathbf{v}, \mathbf{c}]$, it follows that $\mathbf{v}$ is also a connecting vector for $\mathbf{c}$.) All the coordinate basis vectors $\partial/\partial x^\alpha$ are connecting vectors for each other. Conversely, if one is given a set of n linearly independent vectors $\mathbf{e}_1, ..., \mathbf{e}_n$ all of which are connecting for each other within a domain, then there exists a local coordinate system $\{x^\alpha\}$ in that domain such that $\mathbf{e}_\alpha$ is equal to the α-th coordinate basis vector $\partial/\partial x^\alpha$. The flow lines of $\mathbf{e}_1, ..., \mathbf{e}_n$ are the "coordinate grid" of that coordinate system.

Figure 1.1: A visual example of a manifold is a curved surface embedded in the flat 3-dimensional space.

1.2.2 Manifolds and coordinates

If you prefer formal definitions to visual explanations, or if the definitions in Sec. 1.2.1 are entirely familiar, you may skip Sec. 1.2.2 to 1.2.11.

One of the main assumptions underlying GR is that the geometry of our universe is curved rather than flat. In a curved geometry, initially parallel lines may move closer or further apart, and the sum of the angles of some triangles may be larger or smaller than π, depending on the triangle and its location in space. Let us examine the notion of "curved space," starting from an intuitive picture.

A simple visual image of a curved space is a 2-dimensional surface embedded in the 3-dimensional Euclidean (flat) space, as shown in Fig. 1.1. Since the surface is smooth, every sufficiently small patch of the surface looks like a small piece of a flat 2-dimensional space $\mathbb{R}^2$. However, different such patches are glued together in a nontrivial way, so that the entire surface has a shape we perceive as "curved."

According to GR, the geometry of the universe is similar to that of a curved surface. In a sufficiently small neighborhood of each point, the universe looks like the flat four-dimensional Minkowski spacetime $\mathbb{R}^4$, studied in Special Relativity. However, the *global* geometry of the universe (i.e. the geometry observed at sufficiently large distances and time intervals) is different from the Minkowski geometry.

This motivates us to consider the idea of a "general kind of curved space," that is, a space which is only *locally* similar to $\mathbb{R}^4$ but globally very different from $\mathbb{R}^4$. The mathematical object that formalizes this intuitive idea is called a **manifold**. A standard, formal definition of a manifold is given in Sec. 1.2.1. I will now motivate and explain that definition, using a two-dimensional surface as a main example.

To formalize the idea that a two-dimensional surface $\mathcal{M}$ "locally looks like" $\mathbb{R}^2$, one says that for each point p in $\mathcal{M}$ there is a small patch of $\mathcal{M}$ around p which is mapped bijectively (one-to-one) into some patch of $\mathbb{R}^2$. A patch of $\mathbb{R}^2$ can be described by coordinates $\{x_1, x_2\}$ that vary in some finite ranges. Therefore, there is a one-to-one map assigning values x_1 and x_2 to points of $\mathcal{M}$ in a small patch (see Fig. 1.2). This map is called a **local coordinate system** or a **chart**. We can now formulate a first rough definition: A **manifold** is a set $\mathcal{M}$ such that there is a local coordinate system around every point of $\mathcal{M}$. A manifold can be visualized as a surface that is smooth near each point and does not have "corners" or "spikes." An example of a non-manifold is a sphere with a line connected to it. ()

A typical example of a smooth manifold is the **unit 2-sphere**

Figure 1.2: A local coordinate system $\{x_1, x_2\}$ covers a small patch of a manifold.

specified by the equation

$$x^2 + y^2 + z^2 = 1,$$

where x, y, z are the ordinary Cartesian coordinates in a three-dimensional Euclidean space. The 2-sphere is usually denoted S^2. To establish that S^2 is a manifold, it is sufficient to find a local coordinate system near each point. This is straightforward; for instance, it is easy to see that the first two Cartesian coordinates, $\{x, y\}$, can be used as local coordinates $\{x_1, x_2\}$ in a neighborhood of the north pole $\{0, 0, 1\}$, even in the entire northern hemisphere (but not beyond the equator). The coordinates $\{x, y\}$ cannot be used near the point $\{x, y, z\} = \{0, 1, 0\}$ because, e.g., a part of the straight line segment $\{-1 < x < 1, y = 0.99\}$ in $\mathbb{R}^2$ that maps onto S^2 becomes a small circle in S^2. So the coordinates $\{x, y\}$ do not provide a one-to-one map from any subset of $\mathbb{R}^2$ into S^2 near the point $\{0, 1, 0\}$. However, $\{x, z\}$ can be used as a local coordinate system near $\{0, 1, 0\}$.

As I attempted to illustrate in Fig. 1.2, the relationship between the local coordinates $\{x_1, x_2\}$ and the Cartesian coordinates $\{x, y, z\}$ may be complicated. However, in some cases one can simply select a subset of the Cartesian coordinates (for instance, $\{x, y\}$) and obtain a local coordinate system covering some part of $\mathcal{M}$. The only requirement on the local coordinates is that they should provide a one-to-one correspondence between a patch $\mathcal{U} \subset \mathcal{M}$ and a patch $\mathcal{V} \subset \mathbb{R}^2$. For instance, any straight line segment situated within $\mathcal{V}$ must correspond to a non-self-intersecting line segment in $\mathcal{M}$.

It is important to note that there may be *no global* coordinate system covering the entire manifold $\mathcal{M}$. This is the case, for instance, if the manifold $\mathcal{M}$ is a closed surface, such as a sphere (see Statement 1.2.2.1 below), or a donut-shaped surface (a torus). If a global coordinate system exists, $\mathcal{M}$ must be an infinitely extended (perhaps curved) plane-like surface that never "closes on itself," that is, a surface which is *topologically* the same as $\mathbb{R}^2$.

It is easy to see that the global geometry of the sphere S^2 is different from that of $\mathbb{R}^2$, even though small patches of S^2 look like small patches of $\mathbb{R}^2$.

Statement 1.2.2.1: There exists no global coordinate system (chart) in S^2 that would map S^2 smoothly and one-to-one into $\mathbb{R}^2$. (Proof on page 167.) ■

The often used **spherical coordinates** $\{\theta, \phi\}$, defined by

$$x = r\cos\theta\cos\phi,\ y = r\cos\theta\sin\phi,\ z = r\sin\theta,$$

do not constitute a global coordinate system on S^2 because the mapping $S^2 \to \{\theta, \phi\}$ is not one-to-one at the poles of the sphere, $\theta = \pm\pi/2$. Nevertheless, this flaw is relatively insignificant since only two points (the poles) are problematic. Such points where the chart map is not one-to-one are called **coordinate singularities** of a local coordinate system. Despite the presence of coordinate singularities, the spherical coordinates constitute an "almost global" coordinate system, which is very convenient for many calculations. The singular points $\theta = \pm\pi/2$ sometimes need to be handled specially.

Practice problem: Consider the surface in $\mathbb{R}^3$ specified by the equation $x^2 + y^2 - z^2 = 1$, where $\{x, y, z\}$ are the standard coordinates. Prove that this surface is a two-dimensional manifold by showing how to find local coordinates $\{x_1, x_2\}$ in the neighborhood of an arbitrary point $\{x, y, z\}$ on the surface. Is there a global coordinate system for this manifold? *Answer:* No. ■

Although our considerations so far concerned two-dimensional surfaces embedded in a three-dimensional Euclidean space, it is clear that completely analogous arguments apply to higher-dimensional "hypersurfaces" embedded into an even higher-dimensional Euclidean space. This picture leads to the general definition of an **n-dimensional manifold**: a set of points $\mathcal{M}$ such that each point $p \in \mathcal{M}$ belongs to a chart that maps it into a subset of $\mathbb{R}^n$.

1.2.3 Manifolds: intrinsic picture

A very important idea is to imagine that there are "flat" observers living entirely within the surface $\mathcal{M}$. These observers cannot see the larger space and describe the surface $\mathcal{M}$ exclusively through the relationships between the points of $\mathcal{M}$, without referring to any embedding into a larger space. Such a description is called **intrinsic**. The main fact is that the intrinsic description is sufficient for all purposes relevant to the internal geometry of the manifold. One may certainly introduce an embedding of $\mathcal{M}$ into a larger space[3] — either as a way to describe a particular manifold $\mathcal{M}$ more concisely or as a guide for the intuition,— but the final results must be independent of any such embedding. In any case, it turns out that the intrinsic description of the geometry of $\mathcal{M}$ is more elegant than a description in terms of an embedding into a larger space. Another argument in favor of the intrinsic description is that according to General Relativity, *we are* observers living in a four-dimensional curved manifold (the spacetime), and we do not directly see any higher-dimensional space in which our spacetime is embedded as a "hypersurface." Therefore, we need a way to describe the properties of our spacetime in terms of *intrinsic* measurements, i.e. measurements performed entirely within the spacetime.

An example of an intrinsic property is smoothness. A function is **smooth** (of class C^∞) if it is infinitely many times differentiable. In the embedding picture, one can visualize a smooth n-dimensional manifold $\mathcal{M}$ as an n-dimensional hypersurface smoothly embedded into an N-dimensional Euclidean space with coordinates $\{X^a\}$, $a = 1, ..., N$. Using a fixed smooth embedding of a manifold $\mathcal{M}$ into $\mathbb{R}^N$, one could easily define smoothness of functions and curves on $\mathcal{M}$. These definitions may look like this. A **smooth scalar function** is a map $f : \mathcal{M} \to \mathbb{R}$ which is a smooth function of the coordinates $\{X^a\}$. A **smooth curve** $\gamma(\tau)$ on a manifold $\mathcal{M}$ is a

[3] It is shown in differential geometry (Whitney's embedding theorem [37]) that any manifold can be embedded in a sufficiently high-dimensional Euclidean space.

map $\gamma : \mathbb{R} \to \mathcal{M}$ such that the curve coordinates $X^a(\tau)$ in the embedding space are smooth functions of τ. However, these definitions depend on the embedding of $\mathcal{M}$ into $\mathbb{R}^N$. This dependence can be avoided and equivalent definitions can be given *intrinsically*, using local charts on $\mathcal{M}$ that map patches of $\mathcal{M}$ into patches of $\mathbb{R}^n$. Here is how one can define a smooth scalar function. Within one chart, a function $f : \mathcal{M} \to \mathbb{R}$ becomes a function $\mathbb{R}^n \to \mathbb{R}$, defined on a patch of $\mathbb{R}^n$. Thus, smoothness of f can be defined as smoothness of each restriction of f to patches of $\mathbb{R}^n$. In brief, a function f is smooth in $\mathcal{M}$ if it is smooth in every chart. Similarly, a curve $\gamma : \mathbb{R} \to \mathcal{M}$ is smooth if its restriction $\gamma : \mathbb{R} \to \mathbb{R}^n$ to each chart is smooth.

If we define smoothness of functions through their restrictions to charts, we need to consider what happens within an intersection of two different charts. Could it happen that a function f is smooth according to one chart but not smooth according to the other chart? Let $\mathcal{U}_1, \mathcal{U}_2 \subset \mathcal{M}$ be two different chart domains and $\phi_1 : \mathcal{U}_1 \to \mathbb{R}^n$, $\phi_2 : \mathcal{U}_2 \to \mathbb{R}^n$ the corresponding local coordinate maps. Since ϕ_1 and ϕ_2 are one-to-one maps, we may define a map $\phi_1\phi_2^{-1} : \mathbb{R}^n \to \mathbb{R}^n$. (This map is defined in a small patch of $\mathbb{R}^n$ which is the image of the intersection of $\mathcal{U}_1$ and $\mathcal{U}_2$ under ϕ_2.) We may call this map a **coordinate change map**. If *every* coordinate change map (for every pair of intersecting charts) is a smooth map $\mathbb{R}^n \to \mathbb{R}^n$ in the usual sense, i.e. defined by smooth functions in the standard coordinates $\{x_1, ..., x_n\}$, then all charts will agree about the smoothness or otherwise of a function $f : \mathcal{M} \to \mathbb{R}$ or a curve $\gamma : \mathbb{R} \to \mathcal{M}$. Therefore, one adds to the definition of a smooth manifold the requirement that every coordinate change map $\phi_1\phi_2^{-1}$ is smooth, for every pair of intersecting charts. In this way, smoothness of the manifold itself is adequately described by the requirement that the coordinate change maps be smooth.

If there exists a smooth one-to-one map between two entire manifolds, these manifolds are called **diffeomorphic**. For example, the surface $z = x^2 + y^2$ is diffeomorphic to $\mathbb{R}^2$ because there is a one-to-one map between points $\{x, y, z\}$ on the surface and the plane $\{x, y\}$. Thus, just one chart (with $\{x, y\}$ as the coordinates) is sufficient to map this manifold into $\mathbb{R}^2$. On the other hand, a 2-sphere is not diffeomorphic to $\mathbb{R}^2$ (Statement 1.2.2.1).

1.2.4 Tangent spaces

Vectors are used in ordinary physics to specify "directed magnitudes," such as velocities and forces. Therefore, it is important to develop the concept of a "directed magnitude" in a curved space.

To aid the intuition, let us visualize a manifold $\mathcal{M}$ as a surface embedded in a larger space $\mathbb{R}^3$. An immediate example of a "directed magnitude" comes from considering the velocity of a moving point. Hence, let us imagine a point that moves along a **curve** $\gamma(\tau)$ within a manifold, where γ is a map $\mathbb{R} \to \mathcal{M}$. It is clear the velocity of the moving point is a vector (*in the larger space*) that is always tangent to the surface $\mathcal{M}$. Due to this picture, "directed magnitudes" defined within a manifold are sometimes called **tangent vectors**. (Most of the time, we will call them simply **vectors**.)

At every point $p \in \mathcal{M}$, there is a tangent plane to the surface. This tangent plane is a vector subspace of $\mathbb{R}^3$. Considered as a two-dimensional vector space, it is denoted $T_p\mathcal{M}$ and is called the **tangent space** to the manifold $\mathcal{M}$ at point p (see Fig. 1.3). If the manifold $\mathcal{M}$ is an $(n-1)$-dimensional hypersurface embedded into an n-dimensional Euclidean space $\mathbb{R}^n$ then each tangent plane is a vector space of dimension $n-1$.

Figure 1.3: Tangent spaces at points p_1 and p_2 of a manifold, visualized as vector subspaces of $\mathbb{R}^3$.

For instance, consider a hypersurface defined by the equation $f(\mathbf{x}) = 0$, where $\mathbf{x} \in \mathbb{R}^3$. The normal vector $\mathbf{n}$ at a point $\mathbf{x}_0$ has the following components,

$$n_j(\mathbf{x}_0) = \left.\frac{\partial f}{\partial x^j}\right|_{\mathbf{x}=\mathbf{x}_0}.$$

Any vector $\mathbf{t}$ orthogonal to $\mathbf{n}$ is tangent to the hypersurface at the point $\mathbf{x}_0$. Hence, the tangent plane at the point $\mathbf{x}_0$ is the set of points $\mathbf{x}$ in $\mathbb{R}^3$ specified by

$$\mathbf{n} \cdot (\mathbf{x} - \mathbf{x}_0) \equiv \sum_{j=1}^{n} (x^j - x_0^j) n_j(\mathbf{x}_0) = 0.$$

The tangent space is made of vectors with components $x^j - x_0^j$ satisfying this equation. This is a two-dimensional vector space that depends on the point $\mathbf{x}_0$ (i.e. it is a different space for each $\mathbf{x}_0$).

It is important to realize that tangent spaces at different points are *not* naturally related to each other, even though every tangent space is two-dimensional and looks like $\mathbb{R}^2$. For instance,, there is no natural way to add a tangent vector at a point p_1 to a tangent vector at another point p_2, or to subtract these vectors. This should be especially clear from Fig. 1.3, which shows different tangent planes. There is no obvious way to map vectors from one tangent plane into vectors from the other. We will see such a map later when we define an additional structure on the manifold called a "connection." This structure literally provides a connection (i.e. a one-to-one map) between tangent spaces that are infinitesimally close (and thus, in principle, between any two tangent spaces). However, there are infinitely many possible "connections" on a manifold. If we select a single "preferred" connection, in effect we introduce an additional structure on the manifold.

Remark: If an embedding of $\mathcal{M}$ into a Euclidean space is given, there is a way to construct a geometrically preferred connection. One imagines that the manifold $\mathcal{M}$ and the tangent planes are solid surfaces, and that one can "roll" the first tangent plane without sliding and without turning around the surface $\mathcal{M}$ along a certain path in $\mathcal{M}$ until the location of the other plane is reached. This "mechanically" motivated procedure yields a one-to-one map from one tangent plane into another one. The mapping between tangent planes depends

on the path along which we "roll" them, but is unambiguous for *infinitesimally close* points. (It is only the mapping between infinitesimally close tangent spaces that is necessary to determine a connection.) The resulting connection is called the **Levi-Civita connection**; it is defined in Sec. 1.6.6 without referring to the mechanical construction just described. Of course, this connection depends on the embedding of $\mathcal{M}$ into a Euclidean space. ■

So far we considered tangent vectors using the embedding picture, i.e. by imagining that the $\mathcal{M}$ manifold is a hypersurface embedded into a larger space. However, it is much more useful to describe tangent vectors *intrinsically*, i.e. without such an embedding. We can try to define a tangent vector as the "directed velocity" $d\gamma/d\tau$ of some curve $\gamma(\tau)$ going through p. However, we cannot directly differentiate $\gamma(\tau)$ with respect to τ without an embedding because the expression $\gamma(\tau+\delta)-\gamma(\tau)$ is undefined: we cannot "subtract" one point from another. To circumvent this problem without introducing coordinates, we focus not on points but on *functions* of points. (Generally, shifting the attention from an abstract set to *functions defined on the set* is a powerful idea that has proven useful in many areas of mathematics.)

Let $f:\mathcal{M}\to\mathbb{R}$ be a scalar function defined on the manifold $\mathcal{M}$. (A **scalar** function means a function with a numeric value, as opposed to a matrix-valued or a vector-valued function.) Suppose that a curve $\gamma(\tau)$ goes through the point p_0 at $\tau=0$, i.e. that $\gamma(\tau=0)=p_0$, and consider the **directional derivative** of the function $f(p)$ **along the curve** γ at the point p_0. This directional derivative is defined as the derivative of the function $f(\gamma(\tau))$ with respect to τ,

$$\mathrm{D}_\gamma f(p_0)\equiv\left.\frac{d}{d\tau}\right|_{\tau=0}f(\gamma(\tau)).$$

This derivative is interpreted as the instantaneous rate of change of the function f at point p_0, as one moves along the curve γ passing through p_0.

To make the discussion specific, consider the manifold $\mathcal{M}=\mathbb{R}^n$. Since points of $\mathcal{M}$ are arrays of n coordinates $\{x^1,...,x^n\}$, a curve $\gamma(\tau)$ is specified by n functions $\gamma^j(\tau)$. Then the directional derivative $\mathrm{D}_\gamma f$ of a function $f(x^1,...,x^n)$ at a point p_0 is expressed by the formula

$$\mathrm{D}_\gamma f(p_0)=\sum_{k=1}^{n}\frac{d\gamma^k}{d\tau}\left.\frac{\partial f}{\partial x^k}\right|_{\{x^j\}=p_0}.$$

For our present purposes, it is important to view the directional derivative D_γ as a *map* from functions to numbers. The directional derivative D_γ depends not only on the direction of the curve γ, but also on the "speed" at which the points $\gamma(\tau)$ are traversed as τ changes. For instance, the value of $\mathrm{D}_\gamma f$ will be multiplied by 2 if we keep the shape of the curve $\gamma(\tau)$ unchanged but replace the parameter τ by 2τ. Also, we note that $\mathrm{D}_\gamma f$ depends on the behavior of the curve γ in an infinitesimal neighborhood of p_0 but does not depend on the behavior of γ at other points; there are many curves γ that yield the same derivative operation D_γ at the point p_0. Therefore, the operation D_γ carries the information only about the magnitude and the direction of the "intantaneous velocity" along the curve at p_0. This is precisely the information we expect to be represented by a tangent vector at the point p_0. Thus we are motivated to view the *map* D_γ *itself* as the tangent vector. In other words, we are going to define the space of the tangent vectors at p_0, i.e. the tangent space $T_{p_0}\mathcal{M}$, as the vector space consisting of all the possible directional derivatives D_γ at p_0. This will be an *intrinsic* definition of the tangent space because this definition does not make use of any embedding of $\mathcal{M}$ into a larger space. This definition also does not rely on a choice of a local coordinate system because only the *curve* $\gamma(\tau)$ — a set of points in the manifold — that is used to construct the directional derivative.

It might be difficult to visualize the "space of all possible directional derivatives." In order to help the intuition and to describe this "space of derivatives" more explicitly, let us temporarily introduce a local coordinate system $\{x^\alpha\}$ around the point p_0. If the curve $\gamma(\tau)$ is represented in the coordinates $\{x^\alpha\}$ by functions $\gamma^\alpha(\tau)$, we can express the directional derivative $\mathrm{D}_\gamma f$ of a function f as follows,

$$\mathrm{D}_\gamma f(p_0)=\sum_\alpha\left.\frac{\partial f}{\partial x^\alpha}\right|_{p_0}\left.\frac{d\gamma^\alpha}{d\tau}\right|_{\tau=0}=\left[\sum_\alpha\left.\frac{d\gamma^\alpha}{d\tau}\right|_{\tau=0}\left.\frac{\partial}{\partial x^\alpha}\right|_{p_0}\right]f.$$

It is clear from this formula that the derivative operation D_γ is represented by the differential operator

$$\mathrm{D}_\gamma\equiv\sum_\alpha\left.\frac{d\gamma^\alpha}{d\tau}\right|_{\tau=0}\left.\frac{\partial}{\partial x^\alpha}\right|_{p_0}$$

acting on functions f, where $\partial/\partial x^\alpha$ is the partial derivative with respect to one coordinate x^α. Moreover, we see that all the possible directional derivatives D_γ are described by the set of coefficients $\{d\gamma^\alpha/d\tau\}$ multiplying a fixed set of differential operators $\{\partial/\partial x^\alpha\}$. The coefficients $d\gamma^\alpha/d\tau$ depend on the curve γ, while the operators $\partial/\partial x^\alpha$ do not. Therefore, it is natural to regard $\partial/\partial x^\alpha$ as the basis in the vector space of directional derivatives and $d\gamma^\alpha/d\tau$ as the components of D_γ in that basis.

In this way, we have expressed directional derivatives D_γ as differential operators in a local coordinate system. An arbitrary directional derivative can be written as $\sum_\alpha u^\alpha\partial/\partial x^\alpha$, where u^α are some coefficients. Now it is clear that all directional derivatives form a vector space spanned by the basis $\{\partial/\partial x^\alpha\}$. This vector space is the same as the tangent space $T_{p_0}\mathcal{M}$ at p_0 defined above using the embedding picture. This is so because the tangent space $T_{p_0}\mathcal{M}$ in the embedding picture consists of all the possible vectors tangent to $\mathcal{M}$ at p_0, which is the same as the set of velocity vectors of all possible curves $\gamma(\tau)$ at p_0, i.e. the set of all possible values of the components $d\gamma^\alpha/d\tau$. So we may identify the space of tangent vectors to curves at p_0 with the space of directional derivatives at p_0. These are two equivalent descriptions of the tangent space $T_{p_0}\mathcal{M}$. A tangent vector can be understood both as a "direction within the manifold" and, at the same time, as a differential operator acting on scalar functions.

The natural basis $\{\partial/\partial x^\alpha\}$ in the tangent space is called the **coordinate basis** corresponding to a chosen coordinate system $\{x^\alpha\}$.

I will denote tangent vectors by boldface letters such as $\mathbf{v}$ rather than by D_γ, since the curve γ in D_γ plays only an auxiliary role. The action of a tangent vector $\mathbf{v}$ on a function f will be denoted by $\mathbf{v}\circ f$ rather than by $\mathrm{D}_\gamma f$. In local coordinates $\{x^\alpha\}$, one can express the value of a directional derivative (tangent vector) $\mathbf{v}$ at point p_0 applied to a function f as

$$\mathbf{v}\circ f=\sum_\alpha v^\alpha\left.\frac{\partial f}{\partial x^\alpha}\right|_{p_0}, \tag{1.1}$$

where v^α are the components of the vector $\mathbf{v}$ in the basis $\{\partial/\partial x^\alpha\}$. Hence, it is convenient to visualize the vector $\mathbf{v}$ as

the derivative operator

$$\mathbf{v} \equiv \sum_{\alpha} v^{\alpha} \frac{\partial}{\partial x^{\alpha}}.$$

The derivative of a function f at a point p_0 along a curve $\gamma(\tau)$ can be written as

$$\mathrm{D}_{\gamma} f(p_0) \equiv \dot{\gamma}|_{p_0} \circ f,$$

where the notation $\dot{\gamma}|_{p_0}$ means the tangent vector to the curve $\gamma(\tau)$ at point p_0.

Remark on notation: The symbol "$\circ$" is used in general to denote the application of an operation to its argument(s). For instance, a tangent vector $\mathbf{v}$ is by definition a derivative operation, which can be applied to a function f and yields another function, $\mathbf{v} \circ f$. In this notation, "$X \circ Y$" reads "X is applied to Y." Below, I also occasionally use the symbol "$\circ$" to denote the application of a 1-form to a vector and of multilinear forms to sets of vectors. For instance, a bilinear form B applied to two vectors $\mathbf{x}$ and $\mathbf{y}$ yields a number denoted by $B \circ (\mathbf{x}, \mathbf{y})$.

Tangent vectors to curves $\gamma(\tau)$ are denoted $\dot{\gamma}$ where this does not cause confusion. We will not use the notation D_{γ} any more. Coordinate basis vectors such as $\partial/\partial x$ or $\partial/\partial y$ are denoted ∂_x and ∂_y for brevity; in that case, the subscript "x" in ∂_x is *not* an index but a local coordinate, and we will make it clear in the text. Attention will be called to cases when the traditional index notation and the Einstein summation convention, such as $v^{\alpha}\partial_{\alpha}$, are used. These cases will not be common in the text. Usually, summation over indices will be written out explicitly. ■

If a vector $\mathbf{v}$ is given, the components v^{α} in any local coordinate system $\{x^{\alpha}\}$ can be found by substituting the n coordinate functions $f = x^1$, $f = x^2$, ..., $f = x^n$ into Eq. (1.1). Thus, the components v^{α} can be found as

$$v^{\alpha} = \mathbf{v} \circ x^{\alpha}.$$

This is a convenient way to compute the components of a vector in a coordinate system, if the vector is already known through another coordinate system or expressed in another way.

Example: Consider a two-dimensional manifold with local coordinates $\{x, y\}$. Suppose that a curve $\gamma(\tau)$ is specified as

$$\gamma(\tau) = \{x_0(\tau), y_0(\tau)\} = \{\cos\tau, 2\sin\tau\}$$

in these coordinates. Let us compute the tangent vector to the curve, $\mathbf{v}(\tau) \equiv \dot{\gamma}(\tau)$. By definition, the tangent vector $\mathbf{v}$ acts on functions $f(x, y)$ as

$$\mathbf{v} \circ f \equiv \frac{d}{d\tau} f(x_0(\tau), y_0(\tau)).$$

The tangent vectors ∂_x and ∂_y are a basis in the tangent space at any point. The components of $\mathbf{v}$ in the basis $\{\partial_x, \partial_y\}$ are found by using the coordinates x and y instead of f in the above equation. We find

$$v^x = \mathbf{v} \circ x = \frac{d}{d\tau} x_0(\tau) = -\sin\tau,$$
$$v^y = \mathbf{v} \circ y = \frac{d}{d\tau} y_0(\tau) = 2\cos\tau.$$

Thus, $\mathbf{v} = -(\sin\tau)\,\partial_x + 2(\cos\tau)\,\partial_y$. By inspection, we can express $\mathbf{v}$ directly through x and y as

$$\mathbf{v} = -\frac{1}{2} y \partial_x + 2x\partial_y.$$

Using this formula, we can define $\mathbf{v}$ as a vector *field* everywhere (not only on the curve γ). However, there are infinitely many different vector fields $\mathbf{v}$ that coincide with $\dot{\gamma}$ on the curve γ; the vector field $\mathbf{v}$ shown above is just one such field that was, by a coincidence, easy to write down in the present case.

Let us also compute the components of the vector field $\mathbf{v}$ in a different coordinate system. For example, consider a new local coordinate system $\{a, b\}$ defined by

$$a = x + y, \quad b = e^{x-y}.$$

The inverse functions are

$$x = \frac{1}{2}(a + \ln b), \quad y = \frac{1}{2}(a - \ln b).$$

The components of $\mathbf{v}$ are found as

$$v^a = \mathbf{v} \circ a = \left(-\frac{1}{2} y\partial_x + 2x\partial_y\right)(x + y) = -\frac{1}{2} y + 2x,$$
$$v^b = \mathbf{v} \circ b = \left(-\frac{1}{2} y\partial_x + 2x\partial_y\right) e^{x-y} = \left(-\frac{1}{2} y - 2x\right) e^{x-y}.$$

Substituting x, y through a, b, we can express the vector $\mathbf{v}$ in the new coordinate system as

$$\mathbf{v} = \left(\frac{3}{4} a + \frac{5}{4} \ln b\right) \partial_a + \left(-\frac{5}{4} a - \frac{3}{4} \ln b\right) b\partial_b.$$

■

Practice problem: **(a)** Determine the components of the vector $\mathbf{v} = x\partial_x + y\partial_y$ in the coordinate system $\{a, b\}$, where $a = x + y$, $b = 3xy$.
(b) Given the vector $\mathbf{u} = \partial_x + x\partial_y$, find a coordinate system $\{X, Y\}$ (where X and Y are functions of x, y) such that $\mathbf{u} = \partial_X$.

Answers: **(a)** $\mathbf{v} = a\partial_a + 2b\partial_b$. **(b)** One suitable coordinate system is $X = x$, $Y = x^2 - 2y$, and there are infinitely many others. ■

In most calculations involving directional derivatives, we will not actually need to introduce local coordinates $\{x^{\alpha}\}$ and the coordinate basis $\{\partial/\partial x^{\alpha}\}$. Instead, we will use the following properties of vectors, which follow immediately from the fact that vectors are directional derivatives at a point:

$$\mathbf{v} \circ (f + g) = \mathbf{v} \circ f + \mathbf{v} \circ g, \text{ [linearity]} \tag{1.2}$$
$$\mathbf{v} \circ (fg) = (\mathbf{v} \circ f)\, g + f\mathbf{v} \circ g, \text{ [Leibnitz rule]} \tag{1.3}$$
$$\mathbf{v} \circ f = 0 \text{ if } f = \text{const around } p_0. \tag{1.4}$$

For example, one can prove that the chain rule follows from the properties (1.2)-(1.4).

Statement 1.2.4.1: If f is an analytic function $f : \mathbb{R} \to \mathbb{R}$; g is a smooth function $\mathcal{M} \to \mathbb{R}$; and $\mathbf{v}$ is a derivation, then

$$\mathbf{v} \circ (f(g)) = \frac{df(g)}{dg} \mathbf{v} \circ g.$$

(Proof on page 167). ■

Figure 1.4: A short curve segment between points p and p' can be approximated by a tangent vector $\mathbf{v}$.

1.2.5 Tangent vectors as short curve segments

An intuitive picture of an ordinary vector is that of a piece of a straight line with an arrow at one end. In a curved space, there are in general no naturally defined "straight lines," but a sufficiently short line segment can be considered "almost straight." So one can visualize a tangent vector $\mathbf{v} \in T_p\mathcal{M}$ heuristically as a short line segment going from a point p to a neighbor point p'. Let us now explore this heuristic picture, since it provides an important intuitive link between the ordinary geometric notions in flat space and the corresponding notions in the curved space calculus.

To build a correspondence between tangent vectors and line segments, consider a curve $\gamma(\tau)$ that starts at p and goes through p'. Let us assume that p corresponds to $\tau = \tau_0$, that is, $p = \gamma(\tau_0)$, and likewise $p' = \gamma(\tau_0 + \sigma)$, where σ is heuristically a "very small" number. (In other words, we will take the limit $\sigma \to 0$ at the end). Now we would like to define a tangent vector $\mathbf{v}$ that corresponds to the short segment of the curve γ between the points p and p'.

A tangent vector is, by definition, a derivative along a curve (the derivative is applied to scalar functions). So it is natural to consider the derivative of an arbitrary function f along the curve γ at point p,

$$\dot{\gamma} \circ f \equiv \lim_{\delta\tau \to 0} \frac{f(\gamma(\tau_0 + \delta\tau)) - f(\gamma(\tau_0))}{\delta\tau}.$$

While finding the exact value of $\dot{\gamma} \circ f$ requires taking the limit $\delta\tau \to 0$, we will compute $\dot{\gamma} \circ f$ sufficiently precisely if we use the finite value $\delta\tau = \sigma$, provided that σ is sufficiently small. Then we obtain the approximate expression

$$\sigma\dot{\gamma} \circ f \approx f(p') - f(p).$$

The error of this approximation is of order σ^2.

Thus it is natural to identify the tangent vector $\sigma\dot{\gamma}$ as a representation of the short curve segment between the points p and p' (see Fig. 1.4). Let us temporarily denote this vector by $\mathbf{v} \equiv \sigma\dot{\gamma}$. The vector $\mathbf{v}$ does not depend (up to terms of order σ) on the choice of the parameter τ or the curve γ.

Given two "sufficiently close" points p and p', how can we determine the tangent vector $\mathbf{v}$ that represents the "almost straight" line between p and p'? We can choose some curve $\gamma(\tau)$ passing through these points, such that $\gamma(\tau_0) = p$ and $\gamma(\tau_1) = p'$. We can compute the vector $\dot{\gamma}$ at the point p, and then the formula for $\mathbf{v}$ is

$$\mathbf{v} = (\tau_1 - \tau_0)\,\dot{\gamma}(\tau_0) \in T_p\mathcal{M}.$$

The tangent vector $\mathbf{v}$ represents the "arrow between the points" p and p' in the sense of the formula

$$f(p') - f(p) \approx \mathbf{v} \circ f, \tag{1.5}$$

which is approximately valid for *any* smooth function f up to second-order corrections.

1.2.6 *Tangent space as space of derivations

In this section we will see that the properties (1.2)-(1.4) are a minimal necessary set of properties describing *all* the possible directional derivatives. Therefore, one may forget that D_γ was defined using some curve $\gamma(\tau)$, drop the subscript γ, call any map D from functions to numbers satisfying the above properties a **derivation** at p_0, and define the tangent space $T_{p_0}\mathcal{M}$ as the set of all possible derivations. This somewhat abstract definition of $T_p\mathcal{M}$ is more elegant from the purely mathematical point of view but entirely equivalent to the earlier definitions, because every derivation D satisfying the properties (1.2)-(1.4) is a directional derivative D_γ along some curve γ. In other words, the only way to differentiate a function is to take a derivative along a curve in some direction.

To prove these statements, let us perform explicit calculations in a local coordinate system $\{x^\alpha\}$. If D is a derivation satisfying Eqs. (1.2)-(1.4) and $f(p)$ is a smooth function, then we can apply the chain rule (see Statement 1.2.4.1) and compute

$$\mathrm{D} \circ f(p) = \sum_\alpha \frac{\partial f}{\partial x^\alpha} \mathrm{D} \circ x^\alpha(p),$$

where $\mathrm{D} \circ x^\alpha$ is the application of the derivation D to the scalar coordinate function $x^\alpha(p)$. Hence,

$$\mathrm{D} \circ f(p) = \left[\sum_\alpha (\mathrm{D} \circ x^\alpha) \frac{\partial}{\partial x^\alpha}\right] f(p) \equiv \sum_\alpha u^\alpha \frac{\partial}{\partial x^\alpha},$$

where u^α are coefficients defined by $u^\alpha \equiv \mathrm{D} \circ x^\alpha$. It is always possible to find a curve $\gamma(\tau)$ with the derivatives $d\gamma^\alpha/d\tau = u^\alpha$ at the point p. Thus any derivation D is equivalent to a tangent vector in the previous sense.

1.2.7 Vector fields and flows

A **vector field** on a manifold $\mathcal{M}$ is obtained by choosing a tangent vector $\mathbf{v}|_p$ at each point $p \in \mathcal{M}$. Most of the time, we will only need a vector field defined in a neighborhood of some point, rather than on the entire manifold $\mathcal{M}$.

Another way to visualize a vector field is to imagine that the manifold is filled by nonintersecting curves going through all its points (or at least through every point in some neighborhood); see Fig. 1.5. Such a collection of curves is called a **congruence** of curves or a **flow** of a vector field. If a congruence of curves is given, derivatives along curves at various points p will determine tangent vectors $\mathbf{v}|_p$ at all points and thus define a vector field $\mathbf{v}$. The curves in the congruence are also called the **flow lines** of the vector field $\mathbf{v}$. In our notation, a curve γ is the flow line of a vector field $\mathbf{v}$ iff $\dot{\gamma}(\tau) = \mathbf{v}|_{\gamma(\tau)}$ at every point $p \equiv \gamma(\tau)$ along the curve.

Flow lines of a nonzero, smooth vector field always exist and are unique, due to a well-known theorem of calculus. To see this, consider a local coordinate system $\{x^\alpha\}$ where a vector field $\mathbf{v}$ is specified by its components v^α as $\mathbf{v} = \sum_\alpha v^\alpha \mathbf{e}_\alpha$ (the components v^α can be found as $v^\alpha = \mathbf{v} \circ x^\alpha$). A curve $\gamma(\tau)$ is specified by n coordinate functions $\gamma^\alpha(\tau)$. The condition $\dot{\gamma}(\tau) = \mathbf{v}|_{\gamma(\tau)}$ translates into a system of differential equations,

$$\frac{d\gamma^\alpha(\tau)}{d\tau} = v^\alpha|_{p=\gamma(\tau)}.$$

We may choose the initial condition as $\gamma^\alpha(0) = x^\alpha_{(0)}$, where $x^\alpha_{(0)}$ are the local coordinates of an initial point of the curve.

Figure 1.5: A vector field $\mathbf{v}$ tangent to a congruence of curves, which are the flow lines of $\mathbf{v}$. For each point p, the vector $\mathbf{v}(p)$ belongs to the tangent space $T_p\mathcal{M}$ at p.

Since the vector field $\mathbf{v}$ is smooth, such a system always has a unique solution $\gamma^\alpha(\tau)$, which represents the required curve $\gamma(\tau)$ in the local coordinate system. (Of course, this system of equations may be complicated and so it is not always possible to obtain an *explicit* formula for the solution $\gamma^\alpha(\tau)$. In any case, an approximate solution can be found numerically.) Therefore, the flow lines of a nonzero, smooth vector field always form a congruence that (at least locally) fills space.

Example: Given a vector field $\mathbf{v}$, consider the flow lines of $\mathbf{v}$ going through each point of some neighborhood. Let τ be the parameter along each of the flow lines $\gamma(\tau)$, such that $\dot{\gamma} = \mathbf{v}$ everywhere. This defines τ as a scalar function on the manifold. We can compute the scalar function $\mathbf{v} \circ \tau$. Along every flow line, we have

$$\mathbf{v} \circ \tau = \frac{d}{d\tau}\tau = 1,$$

thus $\mathbf{v} \circ \tau = 1$ everywhere. ■

If $\{x^\mu\}$ are local coordinates around apoint p_0, we can consider a congruence of curves of varying x^0 and constant x^1, x^2, ... The tangent vector field to this congruence is $\partial/\partial x^0$. This congruence consists of "curved coordinate axes" of the coordinate x^0. Similarly, the other coordinate basis vectors $\partial/\partial x^1$, $\partial/\partial x^2$, etc., can be seen as tangent vectors to a congruence of curves made by other coordinate axes.

1.2.8 *Tangent bundle

The set of all the tangent spaces (one tangent space $T_p\mathcal{M}$ for each point $p \in \mathcal{M}$) is denoted $T\mathcal{M}$ and called the **tangent bundle** of the manifold $\mathcal{M}$. The tangent bundle is itself a manifold with dimension $2n$ if $\mathcal{M}$ has dimension n. This manifold is perhaps not easy to visualize as a whole, but we will not need to do anything complicated with the tangent bundle $T\mathcal{M}$ as a manifold. Let us only verify that $T\mathcal{M}$ has the structure of a smooth manifold.

By assumption, $\mathcal{M}$ is a smooth manifold and, as such, can be covered by a set of charts. Consider one such chart that maps a subset $\mathcal{U}$ of $\mathcal{M}$ into a subset $\mathcal{V}$ of $\mathbb{R}^n$. Tangent vectors at points $p \in \mathcal{U}$ are mapped into tangent vectors in $\mathcal{V}$, which are simply vectors in $\mathbb{R}^n$ since $\mathcal{V}$ is a portion of the flat Euclidean space $\mathbb{R}^n$. Therefore, the part of $T\mathcal{M}$ consisting of tangent planes to points $p \in \mathcal{U}$ is one-to-one mapped into $\mathcal{V} \times \mathbb{R}^n$. Since the set $\mathcal{V} \times \mathbb{R}^n$ is a subset of $\mathbb{R}^n \times \mathbb{R}^n = \mathbb{R}^{2n}$, we have established that $T\mathcal{M}$ can be covered by patches, and one can find charts that map these patches into $\mathbb{R}^{2n}$. In other words, the tangent bundle $T\mathcal{M}$ is a smooth $2n$-dimensional manifold.

Remark: It is important to realize that the tangent bundle, as a whole manifold, is not necessarily equivalent (i.e. diffeomorphic) to the direct product $\mathcal{M} \times \mathbb{R}^n$, even though every small patch of $T\mathcal{M}$ is diffeomorphic to a patch of $\mathcal{M} \times \mathbb{R}^n$. The reason is the same as that for the manifold $\mathcal{M}$ not being diffeomorphic to $\mathbb{R}^n$, even though small patches of $\mathcal{M}$ are diffeomorphic to patches of $\mathbb{R}^n$. Namely, the patches may be glued together in a nontrivial way such that the global geometry of $\mathcal{M}$ is different from that of $\mathbb{R}^n$. A detailed consideration would lead us too far into differential topology, so I will give only a qualitative example. Suppose a diffeomorphism $\phi : \mathcal{M} \times \mathbb{R}^n \to T\mathcal{M}$ exists, such that every vector space $p \times \mathbb{R}^n$, where $p \in \mathcal{M}$, is mapped one-to-one onto the vector space $T_p\mathcal{M}$ via an invertible linear transformation. Then for every $p \in \mathcal{M}$ one may apply ϕ to $p \times \{1, 0, 0, ..., 0\} \in \mathcal{M} \times \mathbb{R}^n$ and obtain a nonzero vector $\mathbf{e}_1(p) \in T_p\mathcal{M}$ at every point p. However, such a vector field $\mathbf{e}_1$ sometimes cannot exist; a typical example is the 2-sphere S^2. It is known that there exists no everywhere nonvanishing and smooth tangent vector field on a 2-sphere. This property is called the "impossibility of combing a sphere" (see Statement 6.3.2.1). So it is impossible to choose even a single nonzero vector field $\mathbf{e}_1$ that smoothly varies throughout the sphere. Thus, a diffeomorphism $\phi : S^2 \times \mathbb{R}^2 \to TS^2$ does not exist. A tangent bundle which is diffeomorphic to $\mathcal{M} \times \mathbb{R}^n$ is called **trivial**. It follows that the 2-sphere S^2 has a nontrivial tangent bundle. ■

1.2.9 Tensor fields

A **covector** is a linear map ω from vectors $\mathbf{v}$ into numbers. I assume that you know this standard construction from linear algebra, and I will only summarize the concepts we will need. In the index notation, covectors are denoted by letters with a subscript index, ω_α. In our notation, a covector ω applied to a vector $\mathbf{v}$ gives a number $\omega \circ \mathbf{v}$ (read "ω applied to $\mathbf{v}$"); sometimes we also write $\omega(\mathbf{v})$ for the same thing. (In the index notation, this is $\omega_\alpha v^\alpha$.)

Covectors themselves naturally form a vector space called the **dual space**. The dual space to the tangent space $T_p\mathcal{M}$ is denoted by $T_p^*\mathcal{M}$ and consists of covectors acting on tangent vectors at point p. The space $T_p^*\mathcal{M}$ is also called the **cotangent space** at point p.

A **covector field**, also called a **1-form**, is a choice of a covector $\omega|_p$ from the dual space (cotangent space) $T_p^*\mathcal{M}$ at each point p. A 1-form ω can be seen as a linear map from vector fields to functions on $\mathcal{M}$, by acting pointwise on a vector field $\mathbf{v}$ and producing a scalar function f,

$$\omega : \mathbf{v} \mapsto f; \quad \omega|_p \circ \mathbf{v}|_p \equiv f(p).$$

An example of a 1-form is the mapping of a vector $\mathbf{v}$ into the derivative of a *fixed* function f in the direction $\mathbf{v}$, that is, the map $\mathbf{v} \mapsto \mathbf{v} \circ f$ for a fixed f. Clearly, this is a linear map and hence, by definition, it is a 1-form. This 1-form is called the **gradient** of the function f and is denoted $\mathrm{d}f$. Thus, for a fixed function f we define the 1-form $\mathrm{d}f$ by its action on a vector field $\mathbf{v}$ as follows,

$$(\mathrm{d}f) \circ \mathbf{v} \equiv \mathbf{v} \circ f.$$

Let us recall that tangent vectors can be understood as an approximate representation of short curve segments (see

Sec. 1.2.5). If a vector $\mathbf{v}$ represents a short curve segment between points p and p' then the 1-form $\mathrm{d}f$ acting on $\mathbf{v}$ yields approximately $f(p') - f(p)$, according to Eq. (1.5).

Example: Consider a two-dimensional manifold with a local coordinate system $\{x, y\}$. The gradient of the coordinate function x is the 1-form $\mathrm{d}x$. By definition, this 1-form acts on vector fields $\mathbf{u}$ as $(\mathrm{d}x) \circ \mathbf{u} = \mathbf{u} \circ x$. For instance, if $\mathbf{u} = \partial_x$ then obviously $\mathbf{u} \circ x = 1$. In this notation, we obtain the equation

$$(\mathrm{d}x) \circ \mathbf{u} = (\mathrm{d}x) \circ \partial_x = 1,$$

which may look unusual or even confusing at first glance. However, it is only the notation that is unusual; the results are always consistent.

Consider another vector field $\mathbf{v} = y^2\partial_x$ and a function $f(x, y) = x^2y^3$. The field $\mathbf{v}$ acts on f and produces the function

$$\mathbf{v} \circ f = y^2 \frac{\partial}{\partial x} f(x, y) = 2xy^5.$$

The 1-form $\mathrm{d}f$ can be computed using standard rules of calculus as

$$\mathrm{d}f = 2xy^3\mathrm{d}x + 3x^2y^2\mathrm{d}y.$$

However, note that now $\mathrm{d}f$, $\mathrm{d}x$, and $\mathrm{d}y$ are well-defined objects (1-forms) rather than heuristic "infinitesimals."

The action of the 1-form $\mathrm{d}f$ on the vector $\mathbf{v}$ is, by definition,

$$(\mathrm{d}f) \circ \mathbf{v} \equiv \mathbf{v} \circ f = 2xy^5.$$

Let us see how this result can be obtained using the explicit expressions for $\mathrm{d}f$ and $\mathbf{v}$. We have

$$\begin{aligned}(\mathrm{d}f) \circ \mathbf{v} &= \left(2xy^3\mathrm{d}x + 3x^2y^2\mathrm{d}y\right) \circ y^2\partial_x \\ &= \left(2xy^5\right)\mathrm{d}x \circ \partial_x + \left(3x^2y^4\right)\mathrm{d}y \circ \partial_x.\end{aligned}$$

By definition, $\mathrm{d}x \circ \partial_x = 1$ and $\mathrm{d}x \circ \partial_y = 0$, therefore $(\mathrm{d}f) \circ \mathbf{v} = 2xy^5$ as before. ■

Practice problem: **(a)** Given the vector $\mathbf{v} = \partial_x + x\partial_y$, find all 1-forms $\omega = a(x, y)\mathrm{d}x + b(x, y)\mathrm{d}y$ such that $\omega \circ \mathbf{v} = 0$.
(b) Given the 1-form $\omega = x\mathrm{d}y + y\mathrm{d}x$, find all vectors $\mathbf{v} = a(x, y)\partial_x + b(x, y)\partial_y$ such that $\omega \circ \mathbf{v} = 0$. ■

Similarly to vector fields, one can define **tensor fields** of arbitrary rank. For example, if a linear transformation $L|_p$ is defined in each tangent space $T_p\mathcal{M}$, such that $L|_p\, \mathbf{v}|_p$ is another vector from $T_p\mathcal{M}$, then we have a tensor field L on the manifold $\mathcal{M}$. Also, one defines n-**forms** as totally antisymmetric tensor fields of rank $(0,n)$. (The calculus of n-forms is explained in more detail in Sec. 1.4.) The operations of tensor product $L_1 \otimes L_2$, the exterior product $\omega_1 \wedge \omega_2$ of n-forms, and tensor contraction (for example, the contraction $\omega \circ \mathbf{v}$ of a 1-form and a vector) are naturally defined on tensor fields. These algebraic operations are performed on tensors in each tangent space $T_p\mathcal{M}$ separately.

1.2.10 Commutator of vector fields

Since a vector field $\mathbf{v}$ can be viewed as a (first-order) differential operator acting on functions as $\mathbf{v} : f \mapsto \mathbf{v} \circ f$, one may consider the **commutator** of two such operators,

$$[\mathbf{u}, \mathbf{v}] \circ f \equiv \mathbf{u} \circ (\mathbf{v} \circ f) - \mathbf{v} \circ (\mathbf{u} \circ f). \tag{1.6}$$

It turns out (see Statement 1.2.10.1) that the result is *again a derivation*, i.e. a first-order differential operator acting on functions, even though it may appear at first glance that $[\mathbf{u}, \mathbf{v}] \circ f$ involves second-order derivatives of f. For this reason, the operation $[\mathbf{u}, \mathbf{v}] \circ f$ is equivalent to some vector field acting on f. This vector field is denoted by $[\mathbf{u}, \mathbf{v}]$ and is called the **commutator** of the fields $\mathbf{u}$ and $\mathbf{v}$.

Statement 1.2.10.1: **(a)** It follows from the definition (1.6) and Eqs. (1.2)-(1.3) that the commutator $[\mathbf{u}, \mathbf{v}]$ satisfies the defining properties (1.2)–(1.4) of a derivation. Hence, $[\mathbf{u}, \mathbf{v}]$ is itself a vector field. **(b)** The components c^α of the commutator $[\mathbf{u}, \mathbf{v}]$ in terms of the components u^α and v^α in a local coordinate system $\{x^\alpha\}$ with a coordinate basis $\{\mathbf{e}_\alpha\}$,

$$\mathbf{u} = \sum_\alpha u^\alpha \mathbf{e}_\alpha, \quad \mathbf{v} = \sum_\alpha v^\alpha \mathbf{e}_\alpha, \quad [\mathbf{u}, \mathbf{v}] \equiv \sum_\alpha c^\alpha \mathbf{e}_\alpha,$$

are given by the expression

$$([\mathbf{u}, \mathbf{v}])^\beta \equiv c^\beta = u^\alpha \frac{\partial v^\beta}{\partial x^\alpha} - v^\alpha \frac{\partial u^\beta}{\partial x^\alpha}. \tag{1.7}$$

(c) If $\mathbf{e}_\alpha \equiv \partial/\partial x^\alpha$ are the coordinate basis vector fields defined through a local coordinate system $\{x^\alpha\}$ then $[\mathbf{e}_\alpha, \mathbf{e}_\beta] = 0$.

Proof of Statement 1.2.10.1: **(a)** The properties (1.2) and (1.4) are obvious; the nontrivial one is the Leibnitz rule (1.3). To verify the Leibnitz rule, we compute $[\mathbf{u}, \mathbf{v}] \circ (fg)$, where f and g are smooth functions:

$$\begin{aligned}[\mathbf{u}, \mathbf{v}] \circ (fg) &= \mathbf{u} \circ (g\mathbf{v} \circ f + f\mathbf{v} \circ g) - \mathbf{v} \circ (g\mathbf{u} \circ f + f\mathbf{u} \circ g) \\ &= g\mathbf{u} \circ (\mathbf{v} \circ f) + f\mathbf{u} \circ (\mathbf{v} \circ g) - g\mathbf{v} \circ (\mathbf{u} \circ f) - f\mathbf{v} \circ (\mathbf{u} \circ g) \\ &\quad + (\mathbf{u} \circ g)(\mathbf{v} \circ f) + (\mathbf{u} \circ f)(\mathbf{v} \circ g) \\ &\quad - (\mathbf{v} \circ g)(\mathbf{u} \circ f) - (\mathbf{v} \circ f)(\mathbf{u} \circ g) \\ &= ([\mathbf{u}, \mathbf{v}] \circ f)\, g + f\, [\mathbf{u}, \mathbf{v}] \circ g.\end{aligned}$$

(b) A straightforward calculation using the representation of the basis fields $\mathbf{e}_\alpha$ as differential operators yields

$$\begin{aligned}[\mathbf{u}, \mathbf{v}] &= \sum_{\alpha,\beta} \left(u^\alpha \frac{\partial}{\partial x^\alpha}\right)\left(v^\beta \frac{\partial}{\partial x^\beta}\right) - \sum_{\alpha,\beta} \left(v^\alpha \frac{\partial}{\partial x^\alpha}\right)\left(u^\beta \frac{\partial}{\partial x^\beta}\right) \\ &= \sum_{\alpha,\beta} u^\alpha v^\beta \frac{\partial}{\partial x^\alpha}\frac{\partial}{\partial x^\beta} + \sum_{\alpha,\beta} \left(u^\alpha \frac{\partial v^\beta}{\partial x^\alpha}\right)\frac{\partial}{\partial x^\beta} \\ &\quad - \sum_{\alpha,\beta} v^\alpha u^\beta \frac{\partial}{\partial x^\alpha}\frac{\partial}{\partial x^\beta} - \sum_{\alpha,\beta} \left(v^\alpha \frac{\partial u^\beta}{\partial x^\alpha}\right)\frac{\partial}{\partial x^\beta} \\ &= \sum_{\alpha,\beta} \left(u^\alpha \frac{\partial v^\beta}{\partial x^\alpha} - v^\alpha \frac{\partial u^\beta}{\partial x^\alpha}\right)\frac{\partial}{\partial x^\beta} \equiv \sum_\beta c^\beta \frac{\partial}{\partial x^\beta}.\end{aligned}$$

This shows that $[\mathbf{u}, \mathbf{v}]$ is indeed a first-order differential operator, and also gives an explicit formula for c^β.

(c) For a smooth function $f(x^1, ..., x^n)$, we have

$$\frac{\partial}{\partial x^\alpha}\frac{\partial}{\partial x^\beta} f = \frac{\partial}{\partial x^\beta}\frac{\partial}{\partial x^\alpha} f$$

according to a well-known theorem of calculus. Therefore the basis vector fields $\mathbf{e}_\alpha$ commute with each other. ■

Remark: Statement 1.2.10.1 presents two ways of proving the fact that $[\mathbf{a}, \mathbf{b}]$ is a first-order differential operation, in parts (a) and (b). The first proof (a) is performed purely algebraically, using the abstract definition of tangent vectors as (unspecified) operations $\mathbf{v} \circ (...)$ with certain properties. The other proof (b) uses a specific representation of tangent vectors as differential operators $\sum_\alpha v^\alpha \partial/\partial x^\alpha$ in a local coordinate system $\{x^\alpha\}$.

Both the proofs have certain advantages and disadvantages. The proof (a) is very general because it uses only some properties of $\mathbf{v} \circ (...)$. So this proof applies not only to directional derivatives but to *any* operation with the properties (1.2)-(1.3), such as the Lie derivative and the covariant derivative that we will use later. The proof (a) applies equally well to derivatives and to finite difference operators, to operators in infinite-dimensional spaces, and so on. The proof (a) is also more "elegant" because it is index-free, does not involve unnecessary structures (such as a local coordinate system and a basis), and does not depend on the explicit representation of vectors in coordinates. This is the kind of proof a mathematician would be looking for.

On the other hand, the proof (b) is conceptually easier to understand (especially for beginners) because it consists of a specific computation in a familiar and elementary context, namely, manipulations with partial derivatives of functions. Also, the result of the proof (b) is a directly usable formula for the components of the vector $[\mathbf{u}, \mathbf{v}]$, while the proof (a) merely shows that $[\mathbf{u}, \mathbf{v}]$ is a well-defined vector. In the text that follows, I will usually not need explicit formulas for components of vectors, and therefore index-free calculations will be preferable. However, in every case one can translate the final results into components in a local coordinate system. ■

It is important to understand the geometric interpretation of the commutator. Imagine drawing the flow lines of two vector fields $\mathbf{a}$ and $\mathbf{b}$ (Fig. 1.6). Let us start from a point p_0, follow the flow line of $\mathbf{a}$ for a small interval $\delta\tau$ of the parameter τ, and then follow the flow line of $\mathbf{b}$ for another interval $\delta\tau$; we will arrive at a point p. If we again start from p_0 but first follow the lines of $\mathbf{b}$ and then the lines of $\mathbf{a}$ for the same parameter distances $\delta\tau$, we will arrive, in general, at a different point p'. In the limit $\delta\tau \to 0$, the points p and p' will become infinitesimally close to each other and to p_0. As shown in Statement 1.2.10.2, the line between p and p' specifies a well-defined vector in the limit $\delta\tau \to 0$, namely the vector $[\mathbf{a}, \mathbf{b}]\,\delta\tau^2$.

Statement 1.2.10.2: Consider an arbitrary smooth function f, vector fields $\mathbf{a}, \mathbf{b}$, and the points p_0, p, p' in the notation of Fig. 1.6. The commutator $[\mathbf{a}, \mathbf{b}]$ describes the difference between $f(p)$ and $f(p')$ in the following way,

$$\lim_{\delta\tau \to 0} \frac{f(p) - f(p')}{\delta\tau^2} = ([\mathbf{a}, \mathbf{b}] \circ f)|_{p_0}.$$

(Proof on page 167.) ■

Practice problem: Assuming a local coordinate system $\{x, y, z\}$, determine the commutators $[\mathbf{a}, \mathbf{b}]$, $[\mathbf{a}, \mathbf{c}]$, and $[\mathbf{b}, \mathbf{c}]$, where $\mathbf{a} = x\partial_x + y\partial_y + z\partial_z$, $\mathbf{b} = x\partial_y - y\partial_x$, $\mathbf{c} = \partial_z$.

Answers: $[\mathbf{a}, \mathbf{b}] = 0$, $[\mathbf{a}, \mathbf{c}] = -\partial_z$, $[\mathbf{b}, \mathbf{c}] = 0$. ■

Figure 1.6: The commutator $[\mathbf{a}, \mathbf{b}]$ of two vector fields measures the discrepancy between the points p and p' obtained by following the flow lines of the vector fields in different order, starting at a point p_0, for small intervals $\delta\tau$ of the parameter. The blue and the black arrows are the vector fields $\mathbf{a}$ and $\mathbf{b}$, while the dotted lines are the flow lines of these vector fields. The point p is obtained by following the line $p_0 \to p_1$ and then the line $p_1 \to p$, while the point p' is obtained by following the line $p_0 \to p_2$ and then $p_2 \to p'$. The small green vector between the points p and p' is equal to $[\mathbf{a}, \mathbf{b}]\,\delta\tau^2$ in the limit of small distances.

1.2.11 Connecting vectors

If two vector fields $\mathbf{a}$ and $\mathbf{b}$ are such that $[\mathbf{a}, \mathbf{b}] = 0$, the vector field $\mathbf{a}$ is called a **connecting vector** for the field $\mathbf{b}$. (Since $[\mathbf{a}, \mathbf{b}] = -[\mathbf{b}, \mathbf{a}]$, the field $\mathbf{b}$ is then also a connecting vector for the field $\mathbf{a}$. One also says that the vector fields $\mathbf{a}$ and $\mathbf{b}$ **commute** with eath other.) The notion of a connecting vector turns out to be very useful in index-free calculations because of the following geometric interpretation.

Consider a vector field $\mathbf{v}$ and a congruence γ of its flow lines (see Fig. 1.7). Suppose that a subset of the flow lines is labeled by an additional real-valued parameter s, so that $\gamma(\tau; s)$ is a

Figure 1.7: Connecting vectors $\mathbf{c}$ (thick arrows) point in the direction of equal parameter τ along a congruence of flow lines of $\mathbf{v}$ (thin lines). Dotted lines are the flow lines of $\mathbf{c}$, which are also the lines of equal τ.

smooth function $\mathbb{R} \times \mathbb{R} \to \mathcal{M}$ and the tangent vector $\mathbf{v}$ is expressed as $\mathbf{v} =$ "$\partial\gamma/\partial\tau$". Using the function $\gamma(\tau; s)$, we may also consider the curves $\tilde{\gamma}(s) \equiv \gamma(\tau_0; s)$ for a fixed value of $\tau = \tau_0$. The curves $\tilde{\gamma}(s)$ go "straight across" the curves $\gamma(\tau)$, intersecting the latter at points of equal τ. We can then define the tangent vector field $\mathbf{c}$ to the curves $\tilde{\gamma}$ in the usual way, $\mathbf{c} =$ "$\partial\gamma/\partial s$". The geometric interpretation of the vector $\mathbf{c}$ is that it points "sideways" with respect to the curves $\gamma(\tau)$, connecting a point p on a curve $\gamma(\tau; s)$ to a nearby point p' on a neighbor curve, $\gamma(\tau; s')$, where s and s' are "infinitesimally close" while τ stays constant. In other words, the connecting vector $\mathbf{c}$ "connects" neighboring flow lines $\gamma(\tau)$ of the field $\mathbf{v}$ at "corresponding" points, i.e. at points with the same value of the parameter τ. Thus, the flow lines of $\mathbf{c}$ are also lines of constant τ. Now it is easy to check that $\mathbf{c}$ is a connecting vector for $\mathbf{v}$ according to the above definition.

Calculation 1.2.11.1: For the vector fields $\mathbf{v}$ and $\mathbf{c}$ defined in the preceding paragraph through the function $\gamma(\tau; s)$, we have $[\mathbf{c}, \mathbf{v}] = 0$. (Details on page 167.) ■

Since the parameter τ for different flow lines of a given vector field $\mathbf{v}$ can be started with different values at different points, there are infinitely many connecting vector fields for a given field $\mathbf{v}$. The freedom of selecting a connecting field for $\mathbf{v}$ is the same as the freedom of choosing the initial values of the parameter τ on each flow line of $\mathbf{v}$.

If a vector $\mathbf{c}$ is fixed at one point p_0, say $\mathbf{c}(p_0) = \mathbf{c}_0$, one can always select $\mathbf{c}(p)$ in the neighborhood of p_0 in such a way that the field $\mathbf{c}$ commutes with $\mathbf{v}$ everywhere. To find such $\mathbf{c}(p)$, one needs to solve the equation $[\mathbf{c}, \mathbf{v}] = 0$. It is easy to see from the coordinate representation

$$[\mathbf{c}, \mathbf{v}] = \sum_\beta \mathbf{e}_\beta \left(\sum_\alpha c^\alpha \frac{\partial v^\beta}{\partial x^\alpha} - \sum_\alpha v^\alpha \frac{\partial c^\beta}{\partial x^\alpha} \right)$$

that the equation $[\mathbf{c}, \mathbf{v}] = 0$ is a linear differential equation for the unknown vector field $\mathbf{c}$ that involves only the derivative of $\mathbf{c}$ along the flow lines of $\mathbf{v}$. Therefore, it is always possible to solve that equation with any given initial condition $\mathbf{c}_0$.

Remark: Since $[\mathbf{v}, \mathbf{v}] = 0$, every field $\mathbf{v}$ can be formally considered as a connecting field for itself, although there seems to be no useful geometric interpretation of that statement. ■

Vector fields ∂_{x^μ} defined through a coordinate system $\{x^\mu\}$ always commute. In general, any vector field $\mathbf{v}$ can be considered as a coordinate derivative ∂_x in *some* local coordinate system that includes x as one of the coordinates. To show this, it is sufficient to demonstrate that there exists a basis of connecting fields that includes $\mathbf{v}$; then the coordinate system can be constructed by using the flow lines of these vector fields.

Statement 1.2.11.2: For any vector field $\mathbf{v} \neq 0$ given on an N-dimensional manifold $\mathcal{M}$, there exist connecting fields $\mathbf{c}_1, \mathbf{c}_2, ..., \mathbf{c}_{N-1}$ such that $\{\mathbf{v}, \mathbf{c}_1, \mathbf{c}_2, ...\mathbf{c}_{N-1}\}$ is a basis at any point p in a neighborhood of an initial point p_0. (Proof on page 167.) ■

The geometric interpretation of a connecting basis can be understood from Fig. 1.6. If every pair of basis vector fields $\mathbf{e}_a, \mathbf{e}_b$ are connecting, there is no discrepancy between points obtained by following the coordinate lines in different order. The absence of this discrepancy is necessary for the existence of a coordinate system $\{x^\mu\}$ such that $\mathbf{e}_a = \partial/\partial x^a$.

Practice problem: **(a)** In a local coordinate system $\{x, y\}$, determine all connecting vector fields $\mathbf{c}$ for the vector $\mathbf{u} = x\partial_y$, i.e. all $\mathbf{c} = a(x, y)\partial_x + b(x, y)\partial_y$ such that $[\mathbf{c}, \mathbf{u}] = 0$ everywhere.
(b) In a local coordinate system $\{x, y, z\}$, find an explicit basis of connecting vector fields $\mathbf{c}_j$, $j = 1, 2, 3$, for the vector $\mathbf{v} = x\partial_y + y\partial_z$.

Answers: **(a)** $\mathbf{c} = f(x)\mathbf{u} + g(x)\left(x\partial_x + y\partial_y\right)$, where f and g are arbitrary functions of x. **(b)** One such basis is $\mathbf{c}_1 = x\partial_y + y\partial_z$, $\mathbf{c}_2 = \partial_z$, $\mathbf{c}_3 = x^2\partial_x + xy\partial_y + \left(y^2 - xz\right)\partial_z$. ■

1.3 Lie derivative

A vector field $\mathbf{v}$ acts as a directional derivative on scalar functions. The **Lie derivative** $\mathcal{L}_\mathbf{v}$ with respect to a vector field $\mathbf{v}$ is an important differential operation that can be applied not only to scalars but also to all tensor fields. We now deduce the formulas for $\mathcal{L}_\mathbf{v}$ in an **axiomatic way**, i.e. by assuming some desirable properties of this operation. Later we will give a geometric interpretation of $\mathcal{L}_\mathbf{v}$.

We would like $\mathcal{L}_\mathbf{v}$ to act as the usual directional derivative on scalar functions f,

$$\mathcal{L}_\mathbf{v} f = \mathbf{v} \circ f. \tag{1.8}$$

Additionally, $\mathcal{L}_\mathbf{v}$ should have the following properties, fully analogous to Eqs. (1.2)-(1.3), but applicable to arbitrary tensors A, B:

$$\mathcal{L}_\mathbf{v}(A + B) = \mathcal{L}_\mathbf{v}(A) + \mathcal{L}_\mathbf{v}(B), \tag{1.9}$$
$$\mathcal{L}_\mathbf{v}(A \otimes B) = \mathcal{L}_\mathbf{v}(A) \otimes B + A \otimes \mathcal{L}_\mathbf{v}(B), \tag{1.10}$$
$$\mathcal{L}_\mathbf{v}(A \circ B) = \mathcal{L}_\mathbf{v}(A) \circ B + A \circ \mathcal{L}_\mathbf{v}(B), \tag{1.11}$$

where $A \otimes B$ is the tensor product and $A \circ B$ here denotes any "pairing" of the tensors A and B (e.g. $\omega \circ \mathbf{v}$ and also $\mathbf{v} \circ f$ are "pairings" in this sense). As we will see, these properties uniquely define the action of $\mathcal{L}_\mathbf{v}$ on any tensor.

1.3.1 Commutator as Lie derivative

For instance, if f is a scalar and $\mathbf{u}, \mathbf{v}$ are vectors, we expect to have

$$\mathcal{L}_\mathbf{v}(\mathbf{u} \circ f) = [\mathcal{L}_\mathbf{v}(\mathbf{u})] \circ f + \mathbf{u} \circ \mathcal{L}_\mathbf{v}(f).$$

Using Eq. (1.8), this is rewritten as

$$\mathbf{v} \circ (\mathbf{u} \circ f) = [\mathcal{L}_\mathbf{v}(\mathbf{u})] \circ f + \mathbf{u} \circ (\mathbf{v} \circ f).$$

Thus,

$$[\mathcal{L}_\mathbf{v}(\mathbf{u})] \circ f = \mathbf{v} \circ (\mathbf{u} \circ f) - \mathbf{u} \circ (\mathbf{v} \circ f) = [\mathbf{v}, \mathbf{u}] \circ f.$$

In other words, the Lie derivative $\mathcal{L}_\mathbf{v}$ of a vector field $\mathbf{u}$ coincides with the commutator of $\mathbf{v}$ and $\mathbf{u}$,

$$\mathcal{L}_\mathbf{v}\mathbf{u} = [\mathbf{v}, \mathbf{u}] = -\mathcal{L}_\mathbf{u}\mathbf{v}.$$

In the index notation, we have, according to Eq. (1.7),

$$(\mathcal{L}_\mathbf{v}\mathbf{u})^\alpha = \sum v^\beta \frac{\partial u^\alpha}{\partial x^\beta} - u^\beta \frac{\partial v^\alpha}{\partial x^\beta}. \tag{1.12}$$

It is important to realize that the Lie derivative $\mathcal{L}_\mathbf{v}\mathbf{u}$ depends on the *derivatives* of $\mathbf{v}$ (not only on the value of $\mathbf{v}$ and the derivatives of $\mathbf{u}$).

Calculation 1.3.1.1: The Lie derivative $\mathcal{L}_{\mathbf{v}}\mathbf{u}$ involves derivatives of $\mathbf{v}$. In particular, if $\mathbf{u}, \mathbf{v}$ are vector fields and λ is a scalar function then

$$\mathcal{L}_{\lambda\mathbf{v}}\mathbf{u} = \lambda\mathcal{L}_{\mathbf{v}}\mathbf{u} - (\mathbf{u} \circ \lambda)\,\mathbf{v}.$$

To derive this expression, we use the antisymmetry of the commutator and the Leibnitz rule for $\mathcal{L}_{\mathbf{v}}$:

$$\begin{aligned}\mathcal{L}_{\lambda\mathbf{v}}\mathbf{u} &= [\lambda\mathbf{v}, \mathbf{u}] = -[\mathbf{u}, \lambda\mathbf{v}] = -\mathcal{L}_{\mathbf{u}}(\lambda\mathbf{v}) \\ &= -\mathcal{L}_{\mathbf{u}}(\lambda)\,\mathbf{v} - \lambda\mathcal{L}_{\mathbf{u}}(\mathbf{v}) \\ &= -(\mathbf{u} \circ \lambda)\,\mathbf{v} + \lambda\mathcal{L}_{\mathbf{v}}\mathbf{u}.\end{aligned}$$

■

1.3.2 Lie derivative of tensors

Let us continue to investigate the properties of the operation $\mathcal{L}_{\mathbf{v}}$. Consider a 1-form ω and a vector field $\mathbf{u}$. According to Eq. (1.11), we have

$$\mathcal{L}_{\mathbf{v}}(\omega \circ \mathbf{u}) = \mathcal{L}_{\mathbf{v}}(\omega) \circ \mathbf{u} + \omega \circ \mathcal{L}_{\mathbf{v}}(\mathbf{u}).$$

On the other hand, $\omega \circ \mathbf{u}$ is a scalar function, so Eq. (1.8) gives

$$\mathcal{L}_{\mathbf{v}}(\omega \circ \mathbf{u}) = \mathbf{v} \circ (\omega \circ \mathbf{u}).$$

Hence, the Lie derivative of a 1-form ω with respect to $\mathbf{v}$ is the 1-form $\mathcal{L}_{\mathbf{v}}\omega$ that acts on an arbitrary vector $\mathbf{u}$ as

$$(\mathcal{L}_{\mathbf{v}}\omega) \circ \mathbf{u} = \mathbf{v} \circ (\omega \circ \mathbf{u}) - \omega \circ [\mathbf{v}, \mathbf{u}].$$

In the index notation,

$$[\mathcal{L}_{\mathbf{v}}(\omega)]_\mu = v^\alpha \partial_\alpha \omega_\mu + \omega_\alpha \partial_\mu v^\alpha.$$

The action of the Lie derivative on an arbitrary tensor can be derived similarly, using the properties (1.8)–(1.11). For example, suppose A is a bilinear form with vector values, i.e. $A(\mathbf{u}, \mathbf{v})$ is a vector. (The index notation for A would be $A^\lambda_{\alpha\beta}$.) Then the Lie derivative $\mathcal{L}_{\mathbf{w}}A$ is defined as

$$[\mathcal{L}_{\mathbf{w}}A](\mathbf{u}, \mathbf{v}) = [\mathbf{w}, A(\mathbf{u}, \mathbf{v})] - A([\mathbf{w}, \mathbf{u}], \mathbf{v}) - A(\mathbf{u}, [\mathbf{w}, \mathbf{v}]).$$

In the index notation,

$$(\mathcal{L}_{\mathbf{v}}A)^\lambda_{\alpha\beta} = v^\mu \partial_\mu A^\lambda_{\alpha\beta} + A^\lambda_{\alpha\mu}\partial_\beta v^\mu + A^\lambda_{\mu\beta}\partial_\alpha v^\mu - A^\mu_{\alpha\beta}\partial_\mu v^\lambda.$$

The Lie derivative with respect to a coordinate basis vector of a given coordinate system has special properties with respect to that coordinate system.

Statement 1.3.2: Let $\{x^\mu\}$ be local coordinates in a manifold, and consider the standard coordinate bases $\{\partial/\partial x^\mu\} \equiv \{\partial_\mu\}$ and $\{\mathrm{d}x^\mu\}$ in the tangent and the cotangent spaces respectively.

(a) The Lie derivatives with respect to a coordinate basis vector of another basis vector or of a basis 1-form are zero,

$$\mathcal{L}_{\partial_\mu}(\partial_\nu) = 0, \quad \mathcal{L}_{\partial_\mu}(\mathrm{d}x^\nu) = 0.$$

(b) Let us represent an arbitrary tensor of rank (m, n) in the coordinate basis by an array of components. For example, a tensor T of rank $(1, 2)$ is represented by an array $T^\alpha{}_{\beta\gamma}$ as

$$T = \sum_{\alpha,\beta,\gamma} T^\alpha{}_{\beta\gamma} \frac{\partial}{\partial x^\alpha} \otimes \mathrm{d}x^\beta \otimes \mathrm{d}x^\gamma.$$

If it is known that $\mathcal{L}_{\partial/\partial x^1}T = 0$, it means that the component functions $T^\alpha{}_{\beta\gamma}$ are independent of the coordinate x^1.

Proof: (a) The coordinate basis vectors commute since

$$\mathcal{L}_{\partial_\mu}(\partial_\nu) f = \frac{\partial}{\partial x^\mu}\frac{\partial}{\partial x^\nu} f - \frac{\partial}{\partial x^\nu}\frac{\partial}{\partial x^\mu} f = 0$$

for a smooth function f.

The Lie derivative of a 1-form is defined through the action of the 1-form on an arbitrary vector field $\mathbf{v}$,

$$\left(\mathcal{L}_{\partial_\mu}\mathrm{d}x^\nu\right) \circ \mathbf{v} = \mathcal{L}_{\partial_\mu}(\mathrm{d}x^\nu \circ \mathbf{v}) - \mathrm{d}x^\nu \circ \left(\mathcal{L}_{\partial_\mu}\mathbf{v}\right).$$

By definition of the 1-form $\mathrm{d}x^\nu$ we have

$$\mathrm{d}x^\nu \circ \mathbf{v} \equiv \mathbf{v} \circ x^\nu, \quad \mathrm{d}x^\nu \circ \left(\mathcal{L}_{\partial_\mu}\mathbf{v}\right) \equiv \left(\mathcal{L}_{\partial_\mu}\mathbf{v}\right) \circ x^\nu,$$

where x^ν is understood as a scalar function representing the ν-th coordinate of a point. Hence

$$\begin{aligned}\left(\mathcal{L}_{\partial_\mu}\mathrm{d}x^\nu\right) \circ \mathbf{v} &= \partial_\mu(\mathbf{v} \circ x^\nu) - [\partial_\mu, \mathbf{v}] \circ x^\nu \\ &= \mathbf{v} \circ (\partial_\mu \circ x^\nu) = \mathbf{v} \circ \delta^\nu_\mu = 0.\end{aligned}$$

(b) It is sufficient to show the proof on the given example involving a tensor T of rank $(2, 1)$. Using the Leibnitz rule, we compute

$$\begin{aligned}0 = \mathcal{L}_{\partial_1}T &= \sum_{\alpha,\beta,\gamma}\left(\mathcal{L}_{\partial_1}T^\alpha{}_{\beta\gamma}\right)\partial_\alpha \otimes \mathrm{d}x^\beta \otimes \mathrm{d}x^\gamma \\ &= \sum_{\alpha,\beta,\gamma}\left(\frac{\partial}{\partial x^1}T^\alpha{}_{\beta\gamma}\right)\partial_\alpha \otimes \mathrm{d}x^\beta \otimes \mathrm{d}x^\gamma,\end{aligned}$$

since $\mathcal{L}_{\partial_1}\partial_\alpha = 0$ and $\mathcal{L}_{\partial_1}\mathrm{d}x^\beta = 0$ for every α, β. Since the set of basic tensors of the form $\partial_\alpha \otimes \mathrm{d}x^\beta \otimes \mathrm{d}x^\gamma$ is linearly independent, it follows that every derivative $\partial_1 T^\alpha{}_{\beta\gamma}$ vanishes.

■

1.3.3 Geometric interpretation

To illustrate the geometric significance of the Lie derivative, we first note that the Lie derivative of a connecting vector field is zero. A connecting vector, such as $\mathbf{c}$ in Fig. 1.7, is transported from the initial point by the flow of the field $\mathbf{v}$. We can imagine that the entire neighborhood of points around the initial point p is transported along the flow lines of $\mathbf{v}$ to another nearby point p'; this neighborhood is deformed in a certain way by the transport. The character of this deformation is determined by the vector field $\mathbf{v}$ in the neighborhood of the initial point p and along the way to p'. Tangent vectors at p can be visualized as directions towards points near p. So all tangent vectors $\mathbf{a}, \mathbf{b}, \ldots \in T_p\mathcal{M}$ are also transported to particular tangent vectors $\mathbf{a}', \mathbf{b}', \ldots \in T_{p'}\mathcal{M}$ (see Fig. 1.8). Thus the flow of $\mathbf{v}$ determines a map between tangent spaces $T_p\mathcal{M}$ and $T_{p'}\mathcal{M}$, as long as the points p and p' lie on a single flow line of $\mathbf{v}$.

We have already seen (Sec. 1.2.11) that a vector field $\mathbf{u}$ obtained by transporting an initial vector $\mathbf{u}|_p$ along the flow of $\mathbf{v}$ satisfies $\mathcal{L}_{\mathbf{v}}\mathbf{u} = 0$. (The transport from an initial point defines the vector field $\mathbf{u}$ along a single flow line of $\mathbf{v}$, so we need to use many flow lines and many initial values to define the vector field $\mathbf{u}$ everywhere.) In general, for two vector fields $\mathbf{u}$ and $\mathbf{v}$ we will have $\mathcal{L}_{\mathbf{v}}\mathbf{u} \neq 0$. So we might say (heuristically) that the Lie derivative $\mathcal{L}_{\mathbf{v}}\mathbf{u}$ measures the extent to which a vector field $\mathbf{u}$ fails to be a connecting field for $\mathbf{v}$.

To make these considerations somewhat more precise, let us temporarily denote by $\varphi_\tau : T_p\mathcal{M} \to T_{p'}\mathcal{M}$ the map that transports tangent vectors along the flow lines of $\mathbf{v}$ from point

Figure 1.8: A neighborhood of points around p is transported along the flow lines of a vector field $\mathbf{v}$ to a neighborhood around p'. Initial tangent vectors $\mathbf{a}$ and $\mathbf{b}$ from $T_p\mathcal{M}$ are visualized as directions between nearby points. These vectors are transported into vectors $\mathbf{a}'$ and $\mathbf{b}'$ from $T_{p'}\mathcal{M}$.

p to point p', where τ is the parameter distance between p and p'. (In other words, we introduce a curve γ parameterized by τ such that $\gamma(0) = p$ and $\gamma(\tau) = p'$, while $\dot{\gamma} = \mathbf{v}$ everywhere along γ.) In this notation, the vectors in Fig. 1.8 satisfy

$$\mathbf{a}' = \varphi_\tau(\mathbf{a}), \quad \mathbf{b}' = \varphi_\tau(\mathbf{b}).$$

Now we would like to compute the Lie derivative $\mathcal{L}_\mathbf{v}\mathbf{u}$, where $\mathbf{u}$ is some vector field. Let us compute $\mathcal{L}_\mathbf{v}\mathbf{u}$ at point p; let us assume that τ is very small and so $\mathbf{v}$ is a vector pointing from p to p'. We might try to write the derivative of $\mathbf{u}$ along $\mathbf{v}$ at point p as

$$\lim_{\tau\to 0}\frac{\mathbf{u}|_{p'} - \mathbf{u}|_p}{\tau}, \quad ???$$

but this expression is meaningless since we cannot subtract vectors $\mathbf{u}$ at different points: these vectors belong to different tangent spaces. However, we can transport $\mathbf{u}|_{p'} \in T_{p'}\mathcal{M}$ back to the tangent space $T_p\mathcal{M}$ using the inverse map φ_τ^{-1}. So we write the derivative of $\mathbf{u}$ along $\mathbf{v}$ at point p as

$$\mathcal{L}_\mathbf{v}\mathbf{u} = \lim_{\tau\to 0}\frac{\varphi_\tau^{-1}\left(\mathbf{u}|_{p'}\right) - \mathbf{u}|_p}{\tau}. \tag{1.13}$$

The geometric interpretation of this expression is clear: $\mathcal{L}_\mathbf{v}\mathbf{u}$ is the extent to which the field $\mathbf{u}$ fails to be transported along $\mathbf{v}$.[4]

Similar considerations apply to the Lie derivative of a tensor A with respect to a vector field $\mathbf{v}$. Any tensor A can be defined as a multilinear function of tangent vectors and covectors, while vectors and covectors are defined through the points in an infinitesimal neighborhood of p. Thus, any tensor A is ultimately an object defined through combinations of points near p. When these points are transported by the flow of a vector field $\mathbf{v}$, the corresponding transport $\varphi_\tau(A)$ of the tensor A is also well-defined. Then the Lie derivative $\mathcal{L}_\mathbf{v}A$ is defined by a formula analogous to Eq. (1.13).

It follows from expressions derived above that the Lie derivative $\mathcal{L}_\mathbf{v}A|_p$ of a tensor A at a point p contains not only derivatives of A but also derivatives of $\mathbf{v}$. So the tensor $\mathcal{L}_\mathbf{v}A|_p$ depends not only on the value $\mathbf{v}|_p$ of the vector field $\mathbf{v}$ at the point p but also on the values of $\mathbf{v}$ in an entire neighborhood of p. Thus the Lie derivative $\mathcal{L}_\mathbf{v}A|_p$ is not a true directional derivative of A in the direction of $\mathbf{v}$ at the point p. A true directional derivative along a curve $\gamma(\tau)$, i.e. a derivative that depends only on the *value* of the vector $\dot{\gamma} \equiv \mathbf{v}(p)$ at the point p, must be independent of the *derivatives* of $\mathbf{v}$ at p. Such a true directional derivative cannot be defined without introducing some additional structures on the manifold $\mathcal{M}$. This is so because the tensors $A(p)$ and $A(p')$ at neighboring points belong to different tensor spaces, and thus there is no definition for a quantity such as $A(p') - A(p)$. Similarly, there is no possibility to integrate vectors or tensors over a domain. We might say, in figurative language, that the tangent spaces "are disconnected" and a directional derivative cannot be computed without a "connection" between these spaces. (The structure called the "connection" will be introduced in Sec. 1.6 below.) When we evaluate the Lie derivative $\mathcal{L}_\mathbf{v}$, the information about how to connect the tangent spaces comes from the flow of the vector field $\mathbf{v}$. This allows us to relate directions around p to directions around p', i.e. to "connect" the tangent spaces $T_p\mathcal{M}$ and $T_{p'}\mathcal{M}$. However, this procedure uses information about the vector field $\mathbf{v}$ in the entire neighborhood of p, not just at one point p.

1.4 Calculus of differential forms

The calculus of differential forms is a basic tool of differential geometry. Differential forms are not widely used in standard texts on GR because they do not provide a decisive computational advantage as long as one remains within the standard introductory material. A substantial computational advantage of differential forms is first seen when considering more advanced material, such as the Frobenius theorem or the tetrad formulation of GR. However, the calculus of forms is relatively simple, and in my view the learning effort involved is amply justified by the conceptual advantages and wide-ranging applicability of differential forms in theoretical physics and mathematics. In the following subsections I explain the motivation for introducing differential forms. Then (Sec. 1.4.3 and below) I give an overview of the basic properties of differential forms, mostly without proof. Since the calculus of forms is standard material and since it will be used in this book only as a computational tool, this brief introduction will suffice.[5]

1.4.1 Volume as antisymmetric tensor

The familiar notion of volume can be given a natural interpretation in terms of antisymmetric multilinear functions of vectors, i.e. antisymmetric tensors. This interpretation is a great help in calculations because antisymmetric tensors have rich properties.

We begin with the two-dimensional Euclidean plane $\mathbb{R}^2$. In two dimensions, the *area* plays the role of volume, so let us

[4] Although in this section I do not actually *prove* that Eq. (1.13) is equivalent to the previous definition of $\mathcal{L}_\mathbf{v}\mathbf{u}$, a proof can be straightforwardly filled in or found in differential geometry textbooks, albeit perhaps in a more formal or abstract language.

[5] The calculus of differential forms is explained, for example, in chapter 4 of [33] or in chapter 7 of [1].

consider the area of a parallelogram spanned by two vectors $\mathbf{u}, \mathbf{v}$. According to standard formula of elementary geometry, the area of the parallelogram is

$$A = |\mathbf{u}|\,|\mathbf{v}| \sin\alpha,$$

where α is the angle between the vectors, which is a number between 0 and π determined by

$$\cos\alpha \equiv \frac{\mathbf{u}\cdot\mathbf{v}}{|\mathbf{u}|\,|\mathbf{v}|}.$$

Here $|\mathbf{u}| \equiv \sqrt{\mathbf{u}\cdot\mathbf{u}}$ and $\mathbf{u}\cdot\mathbf{v}$ is the standard Euclidean scalar product. Thus the area of a parallelogram spanned by $\mathbf{u}$ and $\mathbf{v}$ is a nonnegative number defined by

$$A(\mathbf{u},\mathbf{v}) \equiv \sqrt{|\mathbf{u}|^2\,|\mathbf{v}|^2 - (\mathbf{u}\cdot\mathbf{v})^2}.$$

This number appears to be a complicated nonlinear function of the vectors $\mathbf{u}$ and $\mathbf{v}$. It is more convenient to work with the **oriented area** $\tilde{A}$, which is defined as $\tilde{A} = +A$ if the pair $\{\mathbf{u},\mathbf{v}\}$ has positive orientation and $\tilde{A} = -A$ otherwise. (We can fix the "positive orientation" to be that of the coordinate axes $\{x, y\}$ in the plane, taken in this order.) The decisive advantage of the oriented area $\tilde{A}$ over the conventional (unsigned) area A is that $\tilde{A}(\mathbf{u},\mathbf{v})$ turns out to be an *antisymmetric bilinear function* of $\mathbf{u}$ and $\mathbf{v}$. In mathematics, a number-valued bilinear function of two vectors is usually called a **bilinear form**, while an *antisymmetric* bilinear form is called a **2-form**.

The oriented area $\tilde{A}(\mathbf{u},\mathbf{v})$ is by definition antisymmetric in $(\mathbf{u},\mathbf{v})$, since the pair $\{\mathbf{v},\mathbf{u}\}$ has opposite orientation to $\{\mathbf{u},\mathbf{v}\}$. The fact that $\tilde{A}(\mathbf{u},\mathbf{v})$ is an bilinear form can be demonstrated quite straightforwardly. When one of the vectors $\mathbf{u}$ or $\mathbf{v}$ is multiplied by a positive number, the area of a parallelogram is multiplied by the same number. If one of the vectors is multiplied by a negative number, the orientation of the pair $\{\mathbf{u},\mathbf{v}\}$ is reversed and thus $\tilde{A}(\mathbf{u},\mathbf{v})$ changes sign. We also have $\tilde{A}(0,\mathbf{v}) = 0$. So it is easy to see that $\tilde{A}(\lambda\mathbf{u},\mathbf{v}) = \lambda\tilde{A}(\mathbf{u},\mathbf{v})$, where λ is an arbitrary real number (positive, zero, or negative). Since $\tilde{A}(\mathbf{u},\mathbf{v}) = -\tilde{A}(\mathbf{v},\mathbf{u})$, the same property holds for the argument $\mathbf{v}$. Further, one can show by an elementary geometric construction (see Fig. 1.9) that the area does not change when a multiple of $\mathbf{v}$ is added to $\mathbf{u}$, namely

$$\tilde{A}(\mathbf{u}+\lambda\mathbf{v},\mathbf{v}) = \tilde{A}(\mathbf{u},\mathbf{v}).$$

In two dimensions, two vectors $\{\mathbf{u},\mathbf{v}\}$ are a basis if $\tilde{A}(\mathbf{u},\mathbf{v}) \neq 0$. It follows that $\tilde{A}$ is linear in each argument: we can compute $\tilde{A}(\mathbf{u}_1+\mathbf{u}_2,\mathbf{v})$ by decomposing $\mathbf{u}_1 = \lambda_1\mathbf{u}+\mu_1\mathbf{v}$, $\mathbf{u}_2 = \lambda_2\mathbf{u}+\mu_2\mathbf{v}$, and then it is easy to see that

$$\tilde{A}(\mathbf{u}_1+\mathbf{u}_2,\mathbf{v}) = \tilde{A}(\mathbf{u}_1,\mathbf{v}) + \tilde{A}(\mathbf{u}_2,\mathbf{v}).$$

The same property holds for the argument $\mathbf{v}$. Thus, $\tilde{A}(\mathbf{u},\mathbf{v})$ is an antisymmetric bilinear form that we may call the **area 2-form**.

To make the above discussion less abstract, let us express all quantities in Cartesian coordinates $\{x, y\}$. The vectors $\mathbf{u}$ and $\mathbf{v}$ have components $\{u_1, u_2\}$ and $\{v_1, v_2\}$; the unoriented area is

$$A(\mathbf{u},\mathbf{v}) = \sqrt{(u_1^2+u_2^2)\,(v_1^2+v_2^2) - (u_1v_1+u_2v_2)^2}.$$

After some algebraic simplification, this becomes

$$A(\mathbf{u},\mathbf{v}) = \sqrt{(u_1v_2-u_2v_1)^2} = |u_1v_2-u_2v_1|. \tag{1.14}$$

Figure 1.9: The area of the parallelogram spanned by a pair of vectors $\{\mathbf{u},\mathbf{v}\}$ is equal to the area spanned by $\{\mathbf{u}+\lambda\mathbf{v},\mathbf{v}\}$.

Now it is clear that $A(\mathbf{u},\mathbf{v})$ is the absolute value of a 2-form $\tilde{A}$ defined by

$$\tilde{A}(\mathbf{u},\mathbf{v}) = u_1v_2 - u_2v_1 = \begin{vmatrix} u_1 & v_1 \\ u_2 & v_2 \end{vmatrix}.$$

The sign of $\tilde{A}$ is chosen such that the area of the unit square spanned by the unit basis vectors $\{1, 0\}$ and $\{0, 1\}$ (in this order) is equal to 1. We note that the oriented area $\tilde{A}$ is more closely related to linear algebra than the unoriented area A.

A similar argument (with a suitable generalization of Fig. 1.9 to three dimensions) shows that the oriented 3-volume $\tilde{V}(\mathbf{a},\mathbf{b},\mathbf{c})$ of a parallelepiped spanned by three vectors $\mathbf{a},\mathbf{b},\mathbf{c}$ in a three-dimensional Euclidean space is a totally antisymmetric trilinear form (3-form). The same conclusion holds in any dimensions. The n-dimensional oriented volume of a parallelepiped spanned by vectors $\mathbf{a}_1, ..., \mathbf{a}_n$ in Euclidean space is given by

$$\tilde{V}(\mathbf{a}_1,...,\mathbf{a}_n) = \begin{vmatrix} a_1^1 & \cdots & a_n^1 \\ \vdots & \ddots & \vdots \\ a_1^n & \cdots & a_n^n \end{vmatrix},$$

where a_j^i is the i-th component of the vector $\mathbf{a}_j$.

Remark: determinants. The last formula suggests a close connection between antisymmetric forms and the calculus of determinants. Indeed, such a close connection exists. For instance, one can show that the oriented volume of an n-dimensional parallelepiped transformed by a linear map T will change by a numerical factor, which depends on T but does not depend on the parallelepiped. This numerical factor is equal to the determinant of T. In Sec. 1.4.5, we use this property as a convenient *definition* of the determinant of a linear transformation T. ■

A somewhat more complicated concept is the area of a parallelogram spanned by two vectors $\{\mathbf{u},\mathbf{v}\}$ in a higher-dimensional Euclidean space, for example, in $\mathbb{R}^3$. The ordinary (unoriented) area $A(\mathbf{u},\mathbf{v})$ is a nonlinear function of $\mathbf{u},\mathbf{v}$ given by Eq. (1.14). In three (or more) dimensions, one cannot define an "oriented" area $\tilde{A}(\mathbf{u},\mathbf{v})$ linear in $\mathbf{u},\mathbf{v}$. Instead, it turns out that one can define a *vector-valued* antisymmetric, bilinear function $\mathbf{A}(\mathbf{u},\mathbf{v})$ whose absolute value is equal to the area $A(\mathbf{u},\mathbf{v})$. This function is the familiar vector product of the vectors $\mathbf{u}$ and $\mathbf{v}$,

$$\mathbf{A}(\mathbf{u},\mathbf{v}) = \mathbf{u}\times\mathbf{v}.$$

Indeed, it is well known that

$$|\mathbf{u}\times\mathbf{v}| = |\mathbf{u}|\,|\mathbf{v}|\sin\alpha = A(\mathbf{u},\mathbf{v}).$$

Thus, one could say that in three dimensions the area has an orientation *vector*. Thus, it is natural to regard the fundamental area as vector-valued; the ordinary area is then computed as the absolute value of the "area vector."

Remark: The same idea can be generalized to n-dimensional parallelepipeds embedded in N-dimensional space (where $N > n$). This time, it turns out that the "orientation" of the n-dimensional volume is not a vector but an antisymmetric tensor; so the "oriented" n-dimensional volume is naturally tensor-valued. The ordinary volume is a suitable "absolute value" of that tensor. More explanations can be found in Sec. 1.4.4. One may even change the point of view and regard the *oriented* volume as a basic quantity — which is a certain totally antisymmetric tensor — and the ordinary volume as a quantity *defined* as the absolute value of the oriented volume. ■

1.4.2 Motivation for differential forms

In standard courses of multivariate calculus, one studies integrals such as

$$\iiint_{-\infty}^{+\infty} e^{-x^2-y^2-z^2}\,dxdydz = \pi^{3/2}.$$

Expressions such as "$dxdydz$" occurring under the sign of multiple integration are usually explained as a purely symbolic notation. It is perhaps not obvious to a student of calculus that "$dxdydz$" above can be interpreted, quite rigorously, as an *antisymmetric* product of "dx," "dy," and "dz," rather than an ordinary, symmetric product. In fact, the antisymmetric interpretation of "$dxdydz$" is necessary if one wishes to obtain a consistent calculus where objects such as "dx" or "$dxdy$" are well-defined and transform correctly under a change of variables. Differential forms can be understood as the rigorous mathematical objects that make precise sense out of expressions such as "$dxdydz$." In this section we explore these motivational ideas.

Let us begin by considering an example familiar from mechanics. Suppose a particle moves in three-dimensional space along a curve $\mathbf{x}(\tau) \equiv \{X(\tau), Y(\tau), Z(\tau)\}$ and experiences a space-dependent external force $\mathbf{F} \equiv \{F_1, F_2, F_3\}$. The work done by the force can be computed as the **line integral**,

$$W = \int_{\mathbf{x}(\tau)} (F_1 dx + F_2 dy + F_3 dz)\,. \tag{1.15}$$

This expression is computed as the ordinary integral

$$W = \int_{\tau_1}^{\tau_2} \left(F_1\dot{X} + F_2\dot{Y} + F_3\dot{Z}\right) d\tau.$$

However, this form of the expression requires a parameterization $\mathbf{x}(\tau)$, while the work W is actually independent of the choice of the parameter τ along the curve: it depends only on the force $\mathbf{F}$ and on the layout of the given curve in space. So it is more natural to work with the line integral (1.15). We can interpret the integrand in Eq. (1.15) directly as a 1-form

$$\omega \equiv F_1 \mathrm{d}x + F_2 \mathrm{d}y + F_3 \mathrm{d}z.$$

Note that the tangent vector $\dot{\mathbf{x}}d\tau$ is an approximate representation of a short curve segment (see Sec. 1.2.5) between the points $\mathbf{x}(\tau)$ and $\mathbf{x}(\tau + d\tau)$. The expression

$$\left(F_1\dot{X} + F_2\dot{Y} + F_3\dot{Z}\right) d\tau = \omega \circ \dot{\mathbf{x}}d\tau$$

is interpreted as the 1-form ω evaluated on the tangent vector $\dot{\mathbf{x}}d\tau$. This expression represents a small amount of work done along a short curve segment. So the line integral (1.15) is rewritten as

$$W = \int_{\tau_1}^{\tau_2} (\omega \circ \dot{\mathbf{x}})\, d\tau \equiv \int_\gamma \omega,$$

where γ denotes the path along which the particle is moving in space (regardless of the choice of the parameter τ).

Remark: Note that we do not write any "d"s after the integral sign in the last expression; all the "d"s are contained in the 1-form ω. We write the roman "d" in 1-forms to emphasize the fact that "$\mathrm{d}x$" is a separate, rigorously defined object, while "dx" stands for a heuristic "infinitesimal change of x." ■

In general, one defines the integral of a 1-form ω over a curve γ as follows. One splits the curve into a large number N of short segments. Each segment is almost straight and thus can be approximately represented by a tangent vector (see Sec. 1.2.5). Thus we represent the N segments by N tangent vectors $\mathbf{v}_1, ..., \mathbf{v}_N$. Each segment contributes to the integral a small amount computed as $\omega(\mathbf{v}_j) \equiv \omega \circ \mathbf{v}_j$. The integral $\int_\gamma \omega$ is then defined as the limit of the sum of $\omega \circ \mathbf{v}_j$,

$$\int_\gamma \omega = \lim_{N\to\infty} \sum_{j=1}^{N} \omega \circ \mathbf{v}_j.$$

The line integral $\int_\gamma \omega$ can be reduced to an ordinary integral by choosing a parameterization $\gamma(\tau)$ for the curve γ and writing

$$\int_\gamma \omega = \int_{\tau_1}^{\tau_2} (\omega \circ \dot{\gamma})\, d\tau. \tag{1.16}$$

But the result does not depend on the choice of the parameterization. A line integral $\int_\gamma \omega$ is defined purely through splitting of the curve γ into small segments, and so is a geometrically defined quantity independent of the coordinate representation of γ.

The calculus of 1-forms is compatible with the change of variables under the integral. For instance, consider a one-dimensional space and an ordinary integral $\int f(x)dx$. After a change of variable $x = X(\phi)$, the integral becomes

$$\int f(x)\mathrm{d}x = \int f(X(\phi))\frac{dX}{d\phi}\mathrm{d}\phi.$$

This corresponds precisely to the chain rule for the differential operator d,

$$f(x)\mathrm{d}x = f(x)\mathrm{d}X(\phi) = f(x)X'(\phi)\mathrm{d}\phi.$$

So it is consistent to interpret the expression $f(x)dx$ within an ordinary integral as a 1-form $f(x)\mathrm{d}x$.

Let us now consider two-dimensional integrals (**surface integrals**). An integral over a surface with local coordinates $\{x, y\}$ is computed as a repeated integral,

$$\iint F(x,y)dxdy = \int_{x_1}^{x_2} dx \int_{y_1}^{y_2} dy\, F(x,y). \tag{1.17}$$

Now we would like to interpret the expression $F(x,y)dxdy$ as an analog and a generalization of the 1-form $f(x)\mathrm{d}x$ seen in the previous example.

As in the previous example, we can divide the surface of integration into a large number N of small rectangles with sides δx and δy. The sides of each rectangle are apprxoimately represented by a pair of tangent vectors $\{\mathbf{u}_j, \mathbf{v}_j\}$, $j = 1, ..., N$. A rectangle number j located at the point $\{x_j, y_j\}$ gives a small contribution $F(x_j, y_j)\delta x \delta y$ to the integral. It is clear that the number $F(x_j, y_j)\delta x \delta y$ can be understood as the evaluation of a bilinear form ω acting on tangent vectors $\{\mathbf{u}_j, \mathbf{v}_j\}$, i.e.

$$F(x_j, y_j)\delta x \delta y \equiv \omega(\mathbf{u}_j, \mathbf{v}_j).$$

The bilinear form ω is called a **2-form** since it has *two* vector arguments. Then the surface integral is defined as the limit

$$\iint F dx dy = \lim_{N\to\infty} \sum_{j=1}^{N} \omega(\mathbf{u}_j, \mathbf{v}_j).$$

The 2-form ω can be temporarily written as $\omega = F \mathrm{d}x\, \mathrm{d}y$. Let us now explore its properties under the change of variables in the integral.

We first perform a simple change of variables, $\{x, y\} \to \{x, \phi\}$, where we replace y by $y = Y(x, \phi)$ and Y is a fixed function. To transform the integral, it is convenient to use the formula (1.17). Since the variable x is held fixed within the integration over y, we find

$$\int_{x_1}^{x_2} dx \int_{y_1}^{y_2} dy\, F(x, y) = \int_{x_1}^{x_2} dx \int_{\Phi_1(x)}^{\Phi_2(x)} d\phi\, F(x, Y) \frac{\partial Y(x, \phi)}{\partial \phi}.$$

Hence, if we wish to interpret the expression $F \mathrm{d}x\, \mathrm{d}y$ consistently as a bilinear form, we must adopt the rule

$$\mathrm{d}x\, \mathrm{d}Y(x, \phi) = \frac{\partial Y(x, \phi)}{\partial \phi} \mathrm{d}x\, \mathrm{d}\phi.$$

However, according to the calculus of 1-forms, we have

$$\mathrm{d}Y(x, \phi) = \frac{\partial Y}{\partial x}\mathrm{d}x + \frac{\partial Y}{\partial \phi}\mathrm{d}\phi$$

and (assuming that the product $\mathrm{d}x\, \mathrm{d}y$ is bilinear)

$$\mathrm{d}x\, \mathrm{d}Y(x, \phi) = \mathrm{d}x \left(\frac{\partial Y}{\partial x}\mathrm{d}x + \frac{\partial Y}{\partial \phi}\mathrm{d}\phi\right).$$

Therefore, this calculus is consistent with the properties of two-dimensional integration only if we assume that

$$\mathrm{d}x\, \mathrm{d}x = 0.$$

Now it is clear that the 2-form $\mathrm{d}x\, \mathrm{d}y$ must be a rather special kind of product of 1-forms $\mathrm{d}x$ and $\mathrm{d}y$. This product is called the **exterior product** (also **wedge product**) and is denoted by the symbol $\wedge$; so one writes $\mathrm{d}x \wedge \mathrm{d}y$ rather than $\mathrm{d}x\, \mathrm{d}y$. The property

$$\mathrm{d}x \wedge \mathrm{d}x = 0$$

together with bilinearity means that the exterior product is *antisymmetric*. To see this, consider

$$\mathrm{d}(x + y) \wedge \mathrm{d}(x + y) = 0 \;\Rightarrow\; \mathrm{d}x \wedge \mathrm{d}y + \mathrm{d}y \wedge \mathrm{d}x = 0.$$

Let us now check the consistency of a more general change of variables, $\{x, y\} \to \{\phi, \psi\}$ where $x = X(\phi, \psi)$ and $y = Y(\phi, \psi)$. Calculations are straightforward because the only new rule is the antisymmetry of the exterior product. We find

$$\begin{aligned}
\mathrm{d}x \wedge \mathrm{d}y &= \mathrm{d}X(\phi, \psi) \wedge \mathrm{d}Y(\phi, \psi) \\
&= \left(\frac{\partial X}{\partial \phi}\mathrm{d}\phi + \frac{\partial X}{\partial \psi}\mathrm{d}\psi\right) \wedge \left(\frac{\partial Y}{\partial \phi}\mathrm{d}\phi + \frac{\partial Y}{\partial \psi}\mathrm{d}\psi\right) \\
&= \left(\frac{\partial X}{\partial \phi}\frac{\partial Y}{\partial \psi} - \frac{\partial X}{\partial \psi}\frac{\partial Y}{\partial \phi}\right) \mathrm{d}\phi \wedge \mathrm{d}\psi, \qquad (1.18)
\end{aligned}$$

where we used the antisymmetry properties

$$\mathrm{d}\phi \wedge \mathrm{d}\phi = \mathrm{d}\psi \wedge \mathrm{d}\psi = 0, \quad \mathrm{d}\phi \wedge \mathrm{d}\psi + \mathrm{d}\psi \wedge \mathrm{d}\phi = 0,$$

to get the last line. Now we may recognize Eq. (1.18) as the standard formula for the change of variables, involving the two-dimensional Jacobian of the transformation $\{x, y\} \to \{\phi, \psi\}$. In this way, we can see that the unusual rule of the exterior product is a natural consequence of the known properties of multiple integration.[6]

The geometric formulation of the surface integral is therefore the integral of a 2-form over a surface, written as

$$\int_{\mathcal{A}} \omega,$$

where $\mathcal{A}$ is a surface (or part of a surface) and ω is a 2-form.

The same formulation applies to integrals over surfaces embedded in a higher-dimensional space. Consider another example familiar from physics: the flux of a magnetic field $\mathbf{B}$ through a surface $\mathcal{A}$ is computed as a surface integral

$$\Phi = \int_{\mathcal{A}} \mathbf{B} \cdot d\mathbf{S},$$

where $d\mathbf{S}$ is understood as a vector-valued "infinitesimal surface element." The flux integral is usually written in components, $\mathbf{B} \equiv \{B_x, B_y, B_z\}$, as follows:

$$\int_{\mathcal{A}} (B_x dy dz + B_y dx dz + B_z dx dy).$$

However, this notation needs to be supplemented by a complicated prescription for the orientation of the surface elements. Integrals of this kind become more transparent in the notation of 2-forms. One introduces the 2-form

$$\boldsymbol{\beta} \equiv B_x \mathrm{d}y \wedge \mathrm{d}z + B_y \mathrm{d}z \wedge \mathrm{d}x + B_z \mathrm{d}x \wedge \mathrm{d}y$$

and expresses the flux Φ as

$$\Phi = \int_{\mathcal{A}} \boldsymbol{\beta}.$$

The (somewhat complicated) rules for changing variables in such integrals, as well as the orientation prescriptions, are automatically reproduced by the calculus of differential forms. The rules of this calculus are simple: one needs to use the chain rule for d and the antisymmetry of $\wedge$.

Similarly, one can treat a three-dimensional integral,

$$\iiint F(x, y, z) dx dy dz,$$

[6] However, note that we obtained the Jacobian itself rather than its absolute value, which one has in formulas involving the area of domain. This is consistent because integrals of 2-forms are defined on *oriented* surfaces and are not merely integrals of the ordinary, unsigned area. Reversing the orientation of the surface will reverse the sign of the integral.

as an integral of the 3-form $F(x,y,z)\mathrm{d}x\wedge\mathrm{d}y\wedge\mathrm{d}z$ over a three-dimensional manifold (or part of a manifold). The same rules will provide the correct formulas under any changes of variables in the integral. Collectively, n-forms ($n=1,2,3,...$) are called **differential forms** since they represent expressions involving the differentials d.

After this motivation, we proceed to summarize the main definitions and properties of differential forms. We begin by studying totally antisymmetric tensors.

1.4.3 Antisymmetric tensors

An n-**form** ω is a totally antisymmetric map from sets of n vector fields to numbers, $\omega(\mathbf{v}_1,...,\mathbf{v}_n)\in\mathbb{R}$, which is linear in each of its vector arguments $\mathbf{v}_j$. In other words, an n-form is a totally antisymmetric tensor of rank $(0,n)$. The equivalent notations $\omega(\mathbf{v}_1,...\mathbf{v}_n)\equiv\omega\circ(\mathbf{v}_1,...,\mathbf{v}_n)$ will be used for convenience or clarity.

When considering vector fields on manifolds, one deals with vectors $\mathbf{v}|_p$ defined in each tangent space $T_p\mathcal{M}$. So it is natural to consider n-forms $\omega(\mathbf{v}_1,...,\mathbf{v}_n;p)$ defined in each tangent space $T_p\mathcal{M}$, i.e. "n-form fields." These "n-form fields" are called **differential forms** or simply n-forms, just as we sometimes call vector fields simply vectors.

In a local coordinate system $\{x^\alpha\}$, tangent vectors are represented by components v^α and n-forms are represented by multi-indexed arrays of components, $\omega_{\alpha\beta...\gamma}$, such that

$$\omega(\mathbf{v}_1,...,\mathbf{v}_n)=\omega_{\alpha\beta...\gamma}v_1^\alpha v_2^\beta...v_n^\gamma.$$

The array of components $\omega_{\alpha\beta...\gamma}$ is totally antisymmetric in all indices. We use the index-free notation in which n-forms are represented explicitly through basis 1-forms such as $\mathrm{d}x$. To express the antisymmetry of an n-form, one writes $\mathrm{d}x\wedge\mathrm{d}y$, where $\wedge$ denotes the special antisymmetric product to be introduced now.

The **exterior product** (also called the **wedge product**) of two forms, say an m-form ω_1 and an n-form ω_2, is an $(m+n)$-form $\omega_1\wedge\omega_2$, defined by a total antisymmetrization of products of ω_1 and ω_2,

$$(\omega_1\wedge\omega_2)\circ(\mathbf{v}_1,...,\mathbf{v}_{m+n})\equiv\frac{1}{m!n!}\sum_\sigma(-1)^{|\sigma|}\times\omega_1\left(\mathbf{v}_{\sigma(1)},...,\mathbf{v}_{\sigma(m)}\right)\omega_2\left(\mathbf{v}_{\sigma(m+1)},...,\mathbf{v}_{\sigma(m+n)}\right),\tag{1.19}$$

where the sum goes over all the permutations σ of the set $\{1,2,...,m+n\}$, and $|\sigma|=0,1$ is a function showing whether the permutation σ is even or odd. Note that the factors $m!n!$ in Eq. (1.19) will cancel due to the total antisymmetry of ω_1 and ω_2. For instance, if θ is a 1-form and ω is a 2-form then

$$(\theta\wedge\omega)\circ(\mathbf{x},\mathbf{y},\mathbf{z})=\theta(\mathbf{x})\omega(\mathbf{y},\mathbf{z})+\theta(\mathbf{y})\omega(\mathbf{z},\mathbf{x})+\theta(\mathbf{z})\omega(\mathbf{x},\mathbf{y}).$$

Similarly, if η, θ, and ω are 1-forms then

$$(\eta\wedge\theta)\circ(\mathbf{x},\mathbf{y})=\eta(\mathbf{x})\theta(\mathbf{y})-\eta(\mathbf{y})\theta(\mathbf{x})=\det\begin{vmatrix}\eta(\mathbf{x}) & \eta(\mathbf{y})\\ \theta(\mathbf{x}) & \theta(\mathbf{y})\end{vmatrix},$$

$$(\eta\wedge\theta\wedge\omega)\circ(\mathbf{x},\mathbf{y},\mathbf{z})=\det\begin{vmatrix}\eta(\mathbf{x}) & \eta(\mathbf{y}) & \eta(\mathbf{z})\\ \theta(\mathbf{x}) & \theta(\mathbf{y}) & \theta(\mathbf{z})\\ \omega(\mathbf{x}) & \omega(\mathbf{y}) & \omega(\mathbf{z})\end{vmatrix}.$$

The components of $\eta\wedge\theta$ in a local coordinate system $\{x^\alpha\}$ are

$$(\eta\wedge\theta)_{\alpha\beta}=\eta_\alpha\theta_\beta-\theta_\alpha\eta_\beta,$$

where η_α and θ_α are the components of the 1-forms η and θ.

Example: Consider a local coordinate system $\{x,y,z\}$ and the 1-forms $\eta=y\mathrm{d}x-2\mathrm{d}z$, $\theta=x\mathrm{d}y+y\mathrm{d}z$. The exterior product of η and θ is computed as follows,

$$\begin{aligned}\eta\wedge\theta&=(y\mathrm{d}x-2\mathrm{d}z)\wedge(x\mathrm{d}y+y\mathrm{d}z)\\&=xy\mathrm{d}x\wedge\mathrm{d}y+y^2\mathrm{d}x\wedge\mathrm{d}z+2x\mathrm{d}y\wedge\mathrm{d}z\end{aligned}$$

(we used $\mathrm{d}y\wedge\mathrm{d}z=-\mathrm{d}z\wedge\mathrm{d}y$). Let us now compute how the 2-form $\eta\wedge\theta$ acts on a pair of vectors $\mathbf{u}=5\partial_x-y\partial_z$, $\mathbf{v}=\partial_x+3z\partial_y$. We have $\mathrm{d}y\circ\mathbf{u}=0$ and $\mathrm{d}z\circ\mathbf{v}=0$, which simplifies the calculations:

$$\begin{aligned}(\mathrm{d}x\wedge\mathrm{d}y)\circ(\mathbf{u},\mathbf{v})&=(\mathrm{d}x\circ\mathbf{u})(\mathrm{d}y\circ\mathbf{v})=15z,\\(\mathrm{d}x\wedge\mathrm{d}z)\circ(\mathbf{u},\mathbf{v})&=-(\mathrm{d}z\circ\mathbf{u})(\mathrm{d}x\circ\mathbf{v})=y,\\(\mathrm{d}y\wedge\mathrm{d}z)\circ(\mathbf{u},\mathbf{v})&=-(\mathrm{d}z\circ\mathbf{u})(\mathrm{d}y\circ\mathbf{v})=3yz.\end{aligned}$$

Finally, we compute

$$(\eta\wedge\theta)\circ(\mathbf{u},\mathbf{v})=xy\cdot15z+y^2\cdot y+2x\cdot3yz=21xyz+y^3.$$

■

A useful property is that the exterior product of linearly dependent 1-forms vanishes.

Statement 1.4.3.1: If $\omega_1,...,\omega_k$ are some 1-forms, then $\omega_1\wedge...\wedge\omega_k\neq0$ iff the set of the 1-forms $\{\omega_j\}$ is linearly independent.

Proof of Statement 1.4.3.1: If the set $\{\omega_j\}$ is linearly dependent then we can express e.g. ω_1 through other ω_j, and the exterior product vanishes due to antisymmetry ($\omega_j\wedge\omega_j=0$). If the set $\{\omega_j\}$ is linearly independent then it is either already a basis or can be completed to a basis $\{\omega_1,...,\omega_k,...,\omega_n\}$ in the n-dimensional space of 1-forms. So the exterior product is (by definition) an alternating linear combination of tensor products of basis 1-forms,

$$\omega_1\wedge...\wedge\omega_k=\sum_\sigma(-1)^{|\sigma|}\omega_{\sigma(1)}\otimes...\otimes\omega_{\sigma(k)},$$

where the sum is over all permutations σ of the set $\{1,...,k\}$. Since the set of all basis tensors $\{\omega_{j_1}\otimes...\otimes\omega_{j_k}\}$ is by definition linearly independent, the linear combination cannot vanish. ■

1.4.4 *Oriented volume and n-vectors

In Sec. 1.4.1, we have introduced the notion of oriented area and oriented volume. Now we develop a more general picture in which certain antisymmetric tensors represent n-dimensional volumes embedded in N-dimensional space, where dimensions are arbitrary and $N\geq n$.

By analogy with the exterior product of forms, one can define the exterior product of vectors. For instance, the exterior product of two vectors is the antisymmetric tensor defined by

$$\mathbf{x}\wedge\mathbf{y}\equiv\mathbf{x}\otimes\mathbf{y}-\mathbf{y}\otimes\mathbf{x};\quad(\mathbf{x}\wedge\mathbf{y})^{\alpha\beta}=x^\alpha y^\beta-x^\beta y^\alpha.$$

One can consider the vector space of linear combinations of such exterior products; this is the space of antisymmetric tensors of rank (2,0). Similarly, the exterior product of n vectors

is an antisymmetric tensor of rank $(n,0)$. Such totally antisymmetric tensors are sometimes called n-**vectors** or **multivectors**; for instance, $\mathbf{x} \wedge \mathbf{y}$ is called a **bivector**.

Using this construction, one can reinterpret an n-form as a linear map from n-vectors into numbers. For example, a 2-form ω acts on a bivector $\mathbf{x} \wedge \mathbf{y}$ as follows,

$$\omega(\mathbf{x} \wedge \mathbf{y}) = \omega(\mathbf{x} \otimes \mathbf{y} - \mathbf{y} \otimes \mathbf{x}) = \omega(\mathbf{x}, \mathbf{y}) - \omega(\mathbf{y}, \mathbf{x}) = 2\omega(\mathbf{x}, \mathbf{y}).$$

Notice the appearance of an extra factor 2. In the case of n-forms, this extra factor will be $n!$ since we will need to sum over $n!$ possible permutations of n vectors.

Remark: Some textbooks use extra factors of $n!$ when defining the exterior product of n 1-forms; for instance, one could define $(\eta \wedge \theta) \circ (\mathbf{x}, \mathbf{y}) = \frac{1}{2}(\eta(\mathbf{x})\theta(\mathbf{y}) - \eta(\mathbf{y})\theta(\mathbf{x}))$. Then extra factors of $n!$ will appear in some equations but disappear from some other equations. These factors play no essential role, i.e. they are **cosmetic** (they merely make some equations better looking). Of course, one must keep track of the extra factors when one uses formulas from different books. ■

An n-vector $\mathbf{a}_1 \wedge ... \wedge \mathbf{a}_n$ can serve as a representation of the n-dimensional volume of a parallelepiped spanned by a set of n given vectors $\{\mathbf{a}_1, ..., \mathbf{a}_n\}$ in an N-dimensional space (where $N \geq n$). Statement 1.4.4.1 shows that the (oriented) volumes of two such parallelepipeds spanned by the sets $\{\mathbf{a}_1, ..., \mathbf{a}_n\}$ and $\{\mathbf{b}_1, ..., \mathbf{b}_n\}$ are equal iff the two corresponding n-vectors, $\mathbf{a}_1 \wedge ... \wedge \mathbf{a}_n$ and $\mathbf{b}_1 \wedge ... \wedge \mathbf{b}_n$, are equal. This is proved by geometric arguments similar to those in Sec. 1.4.1, and by using an n-dimensional generalization of Fig. 1.9. Note that an analogon of Statement 1.4.3.1 holds also for vectors: an n-vector is nonzero iff the set of its constituent vectors is linearly independent.

Statement 1.4.4.1: We consider an n-dimensional space $\mathbb{R}^n$. **(a)** Every n-vector $\mathbf{a}_1 \wedge ... \wedge \mathbf{a}_n$ is proportional to every other n-vector. **(b)** The ratio of the oriented volumes of two n-dimensional parallelepipeds spanned by the sets $\{\mathbf{a}_1, ..., \mathbf{a}_n\}$ and $\{\mathbf{b}_1, ..., \mathbf{b}_n\}$ are related by the same proportionality factor as the two corresponding n-vectors, $\mathbf{a}_1 \wedge ... \wedge \mathbf{a}_n$ and $\mathbf{b}_1 \wedge ... \wedge \mathbf{b}_n$. (Proof on page 168.) ■

The ordinary (scalar) volume of the parallelepiped spanned by $\{\mathbf{a}_1, ..., \mathbf{a}_n\}$ can be calculated as a suitably defined "absolute value" or the **norm** of the n-vector $\mathbf{a}_1 \wedge ... \wedge \mathbf{a}_n$,

$$\text{Vol}(\mathbf{a}_1, ..., \mathbf{a}_n) = \sqrt{|\mathbf{a}_1 \wedge ... \wedge \mathbf{a}_n|^2}.$$

The norm $|\mathbf{a}_1 \wedge ... \wedge \mathbf{a}_n|$ is defined in the usual manner through the scalar product on the space of n-vectors, which is in turn defined through the scalar product in the vector space. For instance, the area of a parallelogram spanned by two vectors $\{\mathbf{a}, \mathbf{b}\}$ in an N-dimensional Euclidean space $\mathbb{R}^N$ is calculated as follows. The "oriented area" of the parallelogram is represented by the bivector $\mathbf{a} \wedge \mathbf{b}$. Using the standard Cartesian basis $\{\mathbf{e}_1, ..., \mathbf{e}_N\}$ in $\mathbb{R}^N$, one can decompose this bivector into basis bivectors $\{\mathbf{e}_i \wedge \mathbf{e}_j\}$, where $1 \leq i < j \leq N$, with some coefficients A_{ij},

$$\mathbf{a} \wedge \mathbf{b} = \sum_{1 \leq i < j \leq N} A_{ij} \mathbf{e}_i \wedge \mathbf{e}_j.$$

The scalar product is then defined in the space of bivectors by postulating that the bivectors $\{\mathbf{e}_i \wedge \mathbf{e}_j\}$ constitute an orthonormal basis. The scalar product of two arbitrary bivectors is then computed as

$$\left(\sum_{i,j} A_{ij} \mathbf{e}_i \wedge \mathbf{e}_j\right) \cdot \left(\sum_{i,j} A_{ij} \mathbf{e}_i \wedge \mathbf{e}_j\right) = \sum_{i,j} A_{ij} B_{ij}$$

(all the sums are taken over $1 \leq i < j \leq N$). Hence, the ordinary (scalar) area of the parallelogram is

$$\text{Area}(\mathbf{a}, \mathbf{b}) = \sqrt{\sum_{1 \leq i < j \leq N} |A_{ij}|^2}.$$

1.4.5 Determinants

A standard definition of the determinant of a square $n \times n$ matrix A_{ij} is a formula involving the matrix elements:

$$\det(A_{ij}) \equiv \sum_{\sigma} (-1)^{|\sigma|} A_{1\sigma(1)} ... A_{n\sigma(n)},$$

where the sum is performed over all transpositions σ. A "transposition" is a one-to-one map from the set $\{1, 2, ..., n\}$ to the same set. The quantity $|\sigma|$ is defined as 0 when σ is an **even** transposition (equivalent to an even number of pair interchanges) and 1 if σ is an odd transposition. This formula is explicit but complicated. The geometric meaning and the properties of the determinant are much more apparent if one adopts a different (but equivalent) definition.

We define the **determinant** $\det \hat{T}$ of a linear transformation $\hat{T}$ in an n-dimensional Euclidean space $\mathbb{R}^n$ as the volume of the image of the unit cube under the transformation $\hat{T}$. In other words, we select an orthonormal basis $\{\mathbf{e}_1, ..., \mathbf{e}_n\}$ and transform it using $\hat{T}$, obtaining the vectors $\{\hat{T}\mathbf{e}_1, ..., \hat{T}\mathbf{e}_n\}$. By definition, $\det \hat{T}$ is equal to the oriented volume of the n-dimensional parallelepiped spanned by these n vectors.

A little work using the concept of multivectors shows that the the initial set of vectors $\{\mathbf{e}_1, ..., \mathbf{e}_n\}$ does not actually need to be an orthonormal basis; this is desirable, since we can then define the determinant of a transformation $\hat{T}$ without the necessity to have a scalar product in the vector space.

Statement 1.4.5.1: Let $\{\mathbf{v}_1, ..., \mathbf{v}_n\}$ be n arbitrary vectors; denote by $\text{Vol}(\mathbf{v}_1, ..., \mathbf{v}_n)$ the oriented volume of the parallelepiped spanned by these vectors. Consider also the parallelepiped spanned by the transformed vectors $\{\hat{T}\mathbf{v}_1, ..., \hat{T}\mathbf{v}_n\}$. Then the transformed volume is proportional to the original volume with the factor $\det \hat{T}$,

$$\text{Vol}(\hat{T}\mathbf{v}_1, ..., \hat{T}\mathbf{v}_n) = \text{Vol}(\mathbf{v}_1, ..., \mathbf{v}_n) \cdot \det \hat{T}.$$

This factor is independent of the choice of the vectors $\{\mathbf{v}_j\}$. A similar relationship holds for the corresponding multivectors,

$$\hat{T}\mathbf{v}_1 \wedge \hat{T}\mathbf{v}_2 \wedge ... \wedge \hat{T}\mathbf{v}_n = (\mathbf{v}_1 \wedge \mathbf{v}_2 \wedge ... \wedge \mathbf{v}_n) \det \hat{T}.$$

(Proof on page 168.) ■

Due to Statement 1.4.5.1, we can reformulate the definition of the determinant as follows: The determinant of $\hat{T}$ is equal to the factor that multiplies the volume of an *arbitrary* n-dimensional parallelepiped after the transformation $\hat{T}$.

Using this definition, it is easy to derive the fundamental property of determinants: the determinant of a product of two transformations is equal to the product of the two determinants,

$$\det(\hat{A}\hat{B}) = (\det \hat{A})(\det \hat{B}).$$

This property is a simple consequence of the fact that the volume of every parallelepiped transformed by $\hat{A}$ is multiplied by $\det \hat{A}$.

Finally, let us prove an important relationship involving volume in Euclidean space.

Statement 1.4.5.2: The volume of a parallelepiped spanned by vectors $\{\mathbf{v}_1, ..., \mathbf{v}_n\}$ in a Euclidean space $\mathbb{R}^n$ is

$$\text{Vol}\,(\mathbf{v}_1, ..., \mathbf{v}_n) = \sqrt{\det g_{ij}}, \quad g_{ij} \equiv \mathbf{v}_i \cdot \mathbf{v}_j,$$

where $\mathbf{v}_i \cdot \mathbf{v}_j$ is the scalar product of two vectors.

Proof of Statement 1.4.5.2: Let us consider an orthonormal basis $\{\mathbf{e}_j\}$ in this space. The volume of a parallelepiped spanned by $\{\mathbf{e}_j\}$ is, by definition, equal to 1. Since $\{\mathbf{e}_j\}$ is a basis, there exists a linear transformation $\hat{T}$ that brings $\{\mathbf{e}_j\}$ into the given set of vectors $\{\mathbf{v}_j\}$. By Statement 1.4.5.1, the volume of the parallelepiped spanned by $\{\mathbf{v}_j\}$ is equal to $\det \hat{T}$, so it remains to compute that determinant. Let us introduce the components of the transformation $\hat{T}$ in the basis $\{\mathbf{e}_j\}$,

$$\mathbf{v}_j \equiv \hat{T}\mathbf{e}_j = \sum_k T_{jk}\mathbf{e}_k.$$

Since $\mathbf{e}_k \cdot \mathbf{e}_l = \delta_{kl}$, we can express the matrix g_{ij} as

$$g_{ij} = \mathbf{v}_i \cdot \mathbf{v}_j = \left(\sum_k T_{ik}\mathbf{e}_k\right) \cdot \left(\sum_l T_{jl}\mathbf{e}_l\right) = \sum_k T_{ik}T_{jk}.$$

It follows that the matrix g_{ij} is equal to the product of two matrices T_{ij}. Therefore, the determinant of g_{ij} is found as

$$\det g_{ij} = (\det T_{ij})\,(\det T_{ji}) = (\det T_{ij})^2,$$

where we used the fact that the determinant of the transposed matrix is the same as the determinant of the original matrix. Hence,

$$\text{Vol}\,(\mathbf{v}_1, ..., \mathbf{v}_n) = \det T_{ij} = \sqrt{\det g_{ij}},$$

which is the desired formula. ■

1.4.6 Differential forms

Let us now consider **differential forms**, i.e. n-forms defined in the tangent space $T_p\mathcal{M}$ at every point p of a manifold $\mathcal{M}$. An example of a differential form written in local coordinates $\{x, y, z\}$ is

$$\omega = x^2 \mathrm{d}y \wedge \mathrm{d}z - 3y^3 \mathrm{d}x \wedge \mathrm{d}y$$

(in this example, ω is a 2-form).

For scalar functions ("0-forms") f, the 1-form $\mathrm{d}f$ is defined by

$$(\mathrm{d}f) \circ \mathbf{v} \equiv \mathbf{v} \circ f.$$

So the notation "$\mathrm{d}x$" itself can be understood as the differential operator d acting on the function x. It follows that $\mathrm{d}f(x) = f'(x)\mathrm{d}x$, which is a familiar rule of calculus (the chain rule). For this reason, the notation $\mathrm{d}x$ for 1-forms is convenient.

The operator d can be generalized to a linear operator acting on n-forms and producing $(n+1)$-forms; this operator is then called the **exterior differential**. So the exterior differential of an n-form ω is an $(n+1)$-form written as $\mathrm{d}\omega$.

The exterior differential d can be defined either explicitly (see Eq. (1.20) below), or through the properties it satisfies. These properties are the following. For any forms ω_1 and ω_2 and scalar functions f we have the Leibnitz-like rule

$$\mathrm{d}\,(f\omega_1) = \mathrm{d}f \wedge \omega_1 + f\mathrm{d}\omega_1,$$
$$\mathrm{d}(\omega_1 \wedge \omega_2) = (\mathrm{d}\omega_1) \wedge \omega_2 + (-1)^{n_1}\omega_1 \wedge \mathrm{d}\omega_2,$$

where ω_1 is an n_1-form. Heuristically, one gets n sign changes when one "pulls d through an n-form."

The second fundamental property of the exterior differential is $\mathrm{d}\,(\mathrm{d}\omega) = 0$ for any n-form ω. This property can be understood heuristically as follows: "d d" is symmetric with respect to the exchange of d with d; each "d" adds a vector argument into the form, but the result must be a totally antisymmetric form. So we must have $\mathrm{d}\,\mathrm{d} = 0$.

Due to the simplicity of these rules, calculations with differential forms are straightforward.

Example: Consider 1-forms $\omega_1 = x^2\mathrm{d}y$ and $\omega_2 = xy\mathrm{d}x + 2\mathrm{d}y$. The exterior differential of ω_1 is

$$\mathrm{d}\omega_1 = \mathrm{d}\,(x^2\mathrm{d}y) = 2x\mathrm{d}x \wedge \mathrm{d}y + x^2\mathrm{d}\,(\mathrm{d}y) = 2x\mathrm{d}x \wedge \mathrm{d}y,$$

because $\mathrm{d}\,(\mathrm{d}y) = 0$. Let us compute $\mathrm{d}\omega_2$:

$$\begin{aligned}\mathrm{d}\omega_2 &= \mathrm{d}(xy) \wedge \mathrm{d}x + xy\mathrm{d}\,(\mathrm{d}x) + 2\mathrm{d}\,(\mathrm{d}y)\\ &= y\mathrm{d}x \wedge \mathrm{d}x + x\mathrm{d}y \wedge \mathrm{d}x\\ &= -x\mathrm{d}x \wedge \mathrm{d}y,\end{aligned}$$

because $\mathrm{d}x \wedge \mathrm{d}x = 0$ and $\mathrm{d}y \wedge \mathrm{d}x = -\mathrm{d}x \wedge \mathrm{d}y$ due to antisymmetry. Consider now the differential of $\mathrm{d}\omega_2$,

$$\mathrm{d}\,(\mathrm{d}\omega_2) = \mathrm{d}\,(-x\mathrm{d}x \wedge \mathrm{d}y) = -\mathrm{d}x \wedge \mathrm{d}x \wedge \mathrm{d}y = 0.$$

Another example calculation is

$$\mathrm{d}\,(xy\mathrm{d}x \wedge \mathrm{d}z) = \mathrm{d}\,(xy) \wedge \mathrm{d}x \wedge \mathrm{d}z = -x\mathrm{d}x \wedge \mathrm{d}y \wedge \mathrm{d}z.$$

■

A rather cumbersome but explicit formula can be derived for the differential $\mathrm{d}\omega$ of an arbitrary n-form ω. The $(n+1)$-form $\mathrm{d}\omega$ acts on vectors $\mathbf{v}_1, ..., \mathbf{v}_{n+1}$ as follows,

$$\begin{aligned}(\mathrm{d}\omega) \circ (\mathbf{v}_1, ..., \mathbf{v}_{n+1}) \equiv &\sum_{s=1}^{n+1}(-1)^{s-1}\mathbf{v}_s \circ \omega(\mathbf{v}_1, ..., \hat{\mathbf{v}}_s, ..., \mathbf{v}_{n+1})\\ &+ \sum_{1\le r<s\le n+1}(-1)^{r+s-1}\omega([\mathbf{v}_r, \mathbf{v}_s], \mathbf{v}_1, ..., \hat{\mathbf{v}}_r, ..., \hat{\mathbf{v}}_s, ..., \mathbf{v}_{n+1}),\end{aligned} \tag{1.20}$$

where the hat over a vector, $\hat{\mathbf{v}}_s$, indicates the *absence* of the vector $\mathbf{v}_s$ among the listed arguments of ω. As an example of using this formula, consider a 1-form ω, then $\mathrm{d}\omega$ is the 2-form defined by

$$(\mathrm{d}\omega) \circ (\mathbf{x}, \mathbf{y}) \equiv \mathbf{x} \circ (\omega(\mathbf{y})) - \mathbf{y} \circ (\omega(\mathbf{x})) - \omega([\mathbf{x}, \mathbf{y}]). \tag{1.21}$$

It is straightforward to check that this formula actually defines a bilinear map $\mathrm{d}\omega$ that does not contain derivatives of $\mathbf{x}$ or $\mathbf{y}$.

Statement 1.4.6.1: Equation (1.21) defines a bilinear form $\mathrm{d}\omega$ despite the apparent presence of derivatives of $\mathbf{x}$ and $\mathbf{y}$.

Proof of Statement 1.4.6.1: Obviously the formula (1.21) defines an antisymmetric function of $(\mathbf{x}, \mathbf{y})$. So it is sufficient to show that

$$(\mathrm{d}\omega) \circ (\lambda\mathbf{x}, \mathbf{y}) = \lambda(\mathrm{d}\omega) \circ (\mathbf{x}, \mathbf{y})$$

when λ is a scalar function of a point. Once this is proved, it will follow that $\mathrm{d}\omega$ does not contain derivatives of $\mathbf{x}$ or $\mathbf{y}$.

The remaining part of the proof is thus a straightforward calculation:

$$\begin{aligned}(\mathrm{d}\omega)\circ(\lambda\mathbf{x},\mathbf{y}) &= \lambda\mathbf{x}\circ\omega(\mathbf{y})-\mathbf{y}\circ(\lambda\omega(\mathbf{x}))-\omega([\lambda\mathbf{x},\mathbf{y}])\\ &= \lambda\left(\mathbf{x}\circ\omega(\mathbf{y})-\mathbf{y}\circ\omega(\mathbf{x})-\omega([\mathbf{x},\mathbf{y}])\right)\\ &\quad -(\mathbf{y}\circ\lambda)\,\omega(\mathbf{x})+\omega\left((\mathbf{y}\circ\lambda)\,\mathbf{x}\right)\\ &= \lambda(\mathrm{d}\omega)\circ(\mathbf{x},\mathbf{y}).\end{aligned}$$

Here we used Statement 1.3.1.1 to express $[\lambda\mathbf{x},\mathbf{y}]$. ■

There is a useful relationship between the Lie derivative and the exterior differential. For convenience of notation, one introduces the **insertion** operation $\iota_{\mathbf{v}}$ (also called the **interior product**) that "inserts" the vector $\mathbf{v}$ into n-forms as the first argument,

$$(\iota_{\mathbf{v}}\omega)\circ(\mathbf{v}_1,...,\mathbf{v}_{n-1})\equiv\omega(\mathbf{v},\mathbf{v}_1,...,\mathbf{v}_{n-1}).$$

The insertion operator produces $(n-1)$-forms out of n-forms. The Lie derivative can now be expressed through ι and d. To see how, let us first compute $\mathcal{L}_{\mathbf{v}}\omega$ for some 1-form ω and vector field $\mathbf{v}$. The 1-form $\mathcal{L}_{\mathbf{v}}\omega$ acts on an arbitrary vector $\mathbf{u}$ as

$$(\mathcal{L}_{\mathbf{v}}\omega)\circ\mathbf{u}=\mathcal{L}_{\mathbf{v}}(\omega\circ\mathbf{u})-\omega\circ(\mathcal{L}_{\mathbf{v}}\mathbf{u})=\mathbf{v}\circ(\omega(\mathbf{u}))-\omega([\mathbf{v},\mathbf{u}]).$$

Let us compare this with the formula (1.21) for $\mathrm{d}\omega$; by inspection, we notice that

$$(\mathcal{L}_{\mathbf{v}}\omega)\circ\mathbf{u}=(\mathrm{d}\omega)\circ(\mathbf{v},\mathbf{u})+\mathbf{u}\circ(\omega(\mathbf{v})).$$

Using the insertion operator $\iota_{\mathbf{v}}$, we can rewrite this as

$$(\mathcal{L}_{\mathbf{v}}\omega)\circ\mathbf{u}=(\iota_{\mathbf{v}}(\mathrm{d}\omega))\circ\mathbf{u}+\mathbf{u}\circ(\iota_{\mathbf{v}}\omega).$$

Finally, note that $\iota_{\mathbf{v}}\omega$ is a scalar function, so

$$\mathbf{u}\circ(\iota_{\mathbf{v}}\omega)\equiv(\mathrm{d}(\iota_{\mathbf{v}}\omega))\circ\mathbf{u}.$$

Thus

$$(\mathcal{L}_{\mathbf{v}}\omega)\circ\mathbf{u}=(\iota_{\mathbf{v}}(\mathrm{d}\omega)+\mathrm{d}(\iota_{\mathbf{v}}\omega))\circ\mathbf{u}.$$

Omitting the arbitrary vector $\mathbf{u}$, we obtain the **Cartan homotopy formula**

$$\mathcal{L}_{\mathbf{v}}\omega=\mathrm{d}(\iota_{\mathbf{v}}\omega)+\iota_{\mathbf{v}}(\mathrm{d}\omega),$$

written also more concisely as

$$\mathcal{L}_{\mathbf{v}}=\mathrm{d}\iota_{\mathbf{v}}+\iota_{\mathbf{v}}\mathrm{d}. \tag{1.22}$$

This formula holds not only for 1-forms, but also for arbitrary n-forms ω; note that the exterior differential d brings n-forms into $(n+1)$-forms, while $\mathcal{L}_{\mathbf{v}}$ does not change the number of arguments of n-forms. The Cartan homotopy formula for n-forms can be derived directly from the explicit definitions of $\mathrm{d}\omega$ and $\iota_{\mathbf{v}}$ and the Leibnitz property of $\mathcal{L}_{\mathbf{v}}$, for instance by showing that $\iota_{\mathbf{v}}\mathrm{d}\omega=\mathcal{L}_{\mathbf{v}}\omega-\mathrm{d}\iota_{\mathbf{v}}\omega$. See also e.g. the book [33], §4.5.

The following properties also hold for arbitrary n-form ω, n'-form ω', and vector fields $\mathbf{v},\mathbf{x}$:

$$\begin{aligned}\iota_{\mathbf{x}}(\omega\wedge\omega') &= (\iota_{\mathbf{x}}\omega)\wedge\omega'+(-1)^n\,\omega\wedge\iota_{\mathbf{x}}\omega',\\ (\mathcal{L}_{\mathbf{v}}\mathrm{d})\,\omega &= (\mathrm{d}\mathcal{L}_{\mathbf{v}})\,\omega,\\ \mathcal{L}_{\mathbf{v}}(\omega\wedge\omega') &= (\mathcal{L}_{\mathbf{v}}\omega)\wedge\omega'+\omega\wedge\mathcal{L}_{\mathbf{v}}\omega',\\ (\mathcal{L}_{\mathbf{v}}\iota_{\mathbf{x}})\,\omega &= \iota_{[\mathbf{v},\mathbf{x}]}\omega+\iota_{\mathbf{x}}\mathcal{L}_{\mathbf{v}}\omega.\end{aligned}$$

These properties can be verified by straightforward computations which we omit.

1.4.7 *Canonical decomposition of 1-forms and 2-forms

The material is covered in [2], volume 2, chapter 22, Appendix; see also [16], chapter 5.

In this section I review some classical results obtained in the theory of differential forms. The main statements are the following.

With a suitable choice of local coordinates $\{x_1,...,x_n\}$ in a suitable domain of an n-dimensional manifold:

- A given 1-form ω can be expressed in one of two ways: either as
$$\omega=x_1\mathrm{d}x_2+...+x_{2k-1}\mathrm{d}x_{2k},$$
or as
$$\omega=x_1\mathrm{d}x_2+...+x_{2k-1}\mathrm{d}x_{2k}+\mathrm{d}x_{2k+1}.$$
- (The Darboux theorem) A given *closed* 2-form Ω can be expressed as
$$\Omega=\mathrm{d}x_1\wedge\mathrm{d}x_2+...+\mathrm{d}x_{2k-1}\wedge\mathrm{d}x_{2k}.$$
- (The Poincaré lemma) Any closed n-form ω is locally exact: if $\mathrm{d}\omega=0$, there exists an $(n-1)$-form θ such that $\omega=\mathrm{d}\theta$ in some domain (but perhaps not in the entire manifold).

* Canonical decomposition of closed 2-forms (Darboux theorem)

We consider an n-dimensional smooth manifold. In a local coordinate system $\{x_1,...,x_n\}$, an arbitrary 2-form Ω can be expressed as

$$\Omega=\frac{1}{2}\sum_{i,j=1}^{n}\Omega_{ij}(x_1,...,x_n)\mathrm{d}x_i\wedge\mathrm{d}x_j, \tag{1.23}$$

where $\Omega_{ij}=-\Omega_{ji}$ is an x-dependent matrix. However, the coordinate system may be chosen so that a particular 2-form is written in a simpler way. For example, a closed 2-form

$$\boldsymbol{A}=\mathrm{d}x_1\wedge\mathrm{d}x_2+x_3\mathrm{d}x_1\wedge\mathrm{d}x_3$$

can be rewritten as

$$\boldsymbol{A}=\mathrm{d}x_1\wedge\mathrm{d}\left(x_2+\frac{1}{2}x_3^2\right)=\mathrm{d}x_1\wedge\mathrm{d}y_2,\quad y_2\equiv x_2+\frac{1}{2}x_3^2.$$

In this example, a particular choice of the new coordinates $\{x_1,y_2,x_3,...,x_n\}$ reduces the 2-form $\boldsymbol{A}$ to a simpler expression involving just two of the coordinates.

It is useful to know how many different coordinates are needed to represent a given 2-form Ω in the simplest possible way. Of course, it is also useful to be able to determine the new coordinates if a closed 2-form Ω is specified in a given coordinate system.

The **Darboux theorem** (proved below) says that for any closed 2-form Ω a suitable local coordinate system $\{x_1,...,x_n\}$ can be found such that Ω is *locally* (i.e. within a certain domain) expressed as

$$\Omega=\mathrm{d}x_1\wedge\mathrm{d}x_2+\mathrm{d}x_3\wedge\mathrm{d}x_4+...+\mathrm{d}x_{2k-1}\wedge\mathrm{d}x_{2k}, \tag{1.24}$$

where $k\leq n/2$ is some number.

It is advantageous to find such **canonical** local coordinates because then calculations with Ω are much easier. The required number $2k \leq n$ of different coordinates in the decomposition (1.24) is called the **rank** of Ω.

If a closed 2-form Ω is given in a certain coordinate system, can one determine the rank of Ω without knowing the canonical coordinates (but knowing that they exist)? In the example with the 2-form $\boldsymbol{A}$ above, it is easy to guess the correct canonical coordinates. Consider another example,

$$\boldsymbol{B} = \mathrm{d}y_1 \wedge \mathrm{d}y_2 + y_1 \mathrm{d}y_1 \wedge \mathrm{d}y_3.$$

In this case, it is not obvious how to find suitable canonical coordinates $\{x_1, x_2, x_3, ...\}$ such that $\boldsymbol{B}$ is expressed as in Eq. (1.24).

To determine the rank of a given closed 2-form Ω, the following trick can be used. One considers exterior powers of Ω, denoted

$$\Omega^{\wedge k} = \underbrace{\Omega \wedge ... \wedge \Omega}_{k \text{ times}}.$$

Note that for a 2-form Ω the product $\Omega \wedge \Omega$ does not necessarily vanish. A sufficiently high power of Ω will, of course, vanish. So there will be some number $k \leq n/2$ such that

$$\Omega^{\wedge k} \neq 0, \quad \Omega^{\wedge (k+1)} = 0. \tag{1.25}$$

From the Darboux theorem we know that the decomposition (1.24) is possible in some coordinates $\{x_j\}$. In these coordinates, we can compute

$$\Omega^{\wedge k} = k! \, \mathrm{d}x_1 \wedge ... \wedge \mathrm{d}x_{2k} \neq 0,$$

since by assumption all $\{x_j\}$ are independent coordinates in a local coordinate system. However, $\Omega^{\wedge (k+1)} = 0$. Thus the rank of Ω is $2k$, where k is the largest integer such that $\Omega^{\wedge k} \neq 0$ but $\Omega^{\wedge (k+1)} = 0$. If $\Omega = 0$, we say that its rank is zero.

For example, we can immediately see that the 2-form $\boldsymbol{B}$ specified above has rank 2 because $\boldsymbol{B} \wedge \boldsymbol{B} = 0$. Thus, we should expect to find suitable coordinates $\{x_1, x_2, x_3, ...\}$ such that $\boldsymbol{B} = \mathrm{d}x_1 \wedge \mathrm{d}x_2$. Determining these coordinates in practice may be far from easy; a possible method of finding $\{x_j\}$ is given in the proof of the Darboux theorem below.

Remark: The rank of a 2-form may be different at different points of the manifold. Presently, we assume that we will be dealing only with such 2-forms whose rank remains constant *locally*, i.e. throughout some neighborhood of some point. ■

The maximal rank of a 2-form on an n-dimensional manifold is n (for even n) or $n-1$ (for odd n). For a $2k$-dimensional manifold, a 2-form Ω can be **nondegenerate** if the matrix Ω_{ij} is invertible (has nonzero determinant). This condition can be expressed in the following way: for any nonzero vector $\mathbf{x}$ there exists at least one vector $\mathbf{y}$ such that $\Omega(\mathbf{x}, \mathbf{y}) \neq 0$; in other words, the 1-form $\iota_{\mathbf{x}}\Omega$ is a nonvanishing 1-form. Equivalently: if $\iota_{\mathbf{x}}\Omega = 0$ for some vector $\mathbf{x}$ then $\mathbf{x} = 0$.

Statement 1.4.7.1: For a $2k$-dimensional manifold, a 2-form Ω of maximal rank $2k$ is nondegenerate.

Proof: Suppose a vector $\mathbf{x}$ is such that the 1-form $\iota_{\mathbf{x}}\Omega$ vanishes, $\iota_{\mathbf{x}}\Omega = 0$. We would like to prove that $\mathbf{x} = 0$. It follows from $\iota_{\mathbf{x}}\Omega = 0$ that

$$\iota_{\mathbf{x}} \left(\Omega^{\wedge k}\right) = k \left(\iota_{\mathbf{x}}\Omega\right) \wedge \Omega^{\wedge (k-1)} = 0.$$

The $2k$-form $\Omega^{\wedge k}$ is nonzero since Ω has rank $2k$, therefore $\Omega^{\wedge k}$ is proportional to the volume form $\mathrm{d}x_1 \wedge ... \wedge \mathrm{d}x_{2k}$ with a nonzero coefficient. It follows that

$$\iota_{\mathbf{x}} \left(\mathrm{d}x_1 \wedge ... \wedge \mathrm{d}x_{2k}\right) = 0.$$

Writing $\mathbf{x} = \sum_{j=1}^{n} a_j \partial/\partial x_j$, it is straightforward to see that all the coefficients a_j must vanish. Therefore, $\mathbf{x} = 0$. ■

Assuming that the Darboux theorem is true, it is easy to see that a nondegenerate 2-form always has maximal rank. If Ω does not have maximal rank, the canonical decomposition of a 2-form Ω is free of some of the coordinates, say of x_n. It follows that the vector $\mathbf{v} \equiv \partial/\partial x_n$ satisfies $\iota_{\mathbf{v}}\Omega = 0$. Hence, Ω is degenerate.

An algebraic version of the Darboux theorem is the following.

Statement 1.4.7.1: An arbitrary antisymmetric bilinear form (2-form) B can be expressed as

$$B = \theta_1 \wedge \theta_2 + ... + \theta_{2k-1} \wedge \theta_{2k}, \tag{1.26}$$

where θ_j are some suitable 1-forms. The set $\{\theta_j\}$ of these 1-forms is linearly independent. The smallest required number $(2k)$ of these n-forms is the rank of B, which is equal to the rank of the matrix B_{ij} in any basis.

Proof: The choice of a cnonical basis for an antisymmetric bilinear form B is a standard task of finite-dimensional linear algebra. We consider an n-dimensional vector space. If $B = 0$, the rank is zero and the statement is proved. If $B \neq 0$, there exists a vector $\mathbf{e}_1$ such that the 1-form $\iota_{\mathbf{e}_1} B$ is nonzero. Thus there exists another vector $\mathbf{e}_2$ such that $B(\mathbf{e}_1, \mathbf{e}_2) = 1$. Since B is antisymmetric, the vectors $\mathbf{e}_1$ and $\mathbf{e}_2$ cannot be parallel to each other, thus they can be completed to a basis $\{\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3, ..., \mathbf{e}_n\}$. We can choose the other basis vectors $\mathbf{e}_3$, ..., $\mathbf{e}_n$ such that they are orthogonal to $\mathbf{e}_1$ and $\mathbf{e}_2$ with respect to B, i.e.

$$B(\mathbf{e}_1, \mathbf{e}_j) = B(\mathbf{e}_2, \mathbf{e}_j) = 0, \quad j = 3, ..., n.$$

This choice is always possible because we may add to each $\mathbf{e}_j$, $j = 3, ..., n$ a suitable linear combination of $\mathbf{e}_1$ and $\mathbf{e}_2$,

$$\tilde{\mathbf{e}}_j = \mathbf{e}_j - B(\mathbf{e}_1, \mathbf{e}_j)\mathbf{e}_2 + B(\mathbf{e}_2, \mathbf{e}_j)\mathbf{e}_1,$$

so that now $B(\mathbf{e}_1, \tilde{\mathbf{e}}_j) = B(\mathbf{e}_2, \tilde{\mathbf{e}}_j) = 0$ for every $j = 3, ..., n$. For brevity, let us denote the resulting basis again by $\{\mathbf{e}_j\}$. The result of this construction is that the two subspaces spanned by $\{\mathbf{e}_1, \mathbf{e}_2\}$ and by $\{\mathbf{e}_3, ..., \mathbf{e}_n\}$ are orthogonal to each other with respect to the bilinear form B.

After choosing the basis $\{\mathbf{e}_1, ..., \mathbf{e}_n\}$ in this way, we compute the dual basis 1-forms $\{\theta_1, ..., \theta_n\}$ for the basis $\{\mathbf{e}_1, ..., \mathbf{e}_n\}$ and represent the 2-form B as

$$B = \theta_1 \wedge \theta_2 + B^{(1)},$$

where the new 2-form $B^{(1)}$ is equal to zero on $\mathbf{e}_1, \mathbf{e}_2$. Hence, it is sufficient to consider the 2-form $B^{(1)}$ within the $(n-2)$-dimensional subspace spanned by $\{\mathbf{e}_3, ..., \mathbf{e}_n\}$. We can now apply the same construction to $B^{(1)}$ in a smaller number of dimensions; either $B^{(1)} = 0$, or we can find θ_3 and θ_4 such that $B^{(1)} = \theta_3 \wedge \theta_4 + B^{(2)}$, etc. The construction eventually stops because at every step the dimensionality of the space is reduced by two. At that point, we will obtain a decomposition

of the form (1.26), where all 1-forms θ_j are (by construction) a linearly independent set.

In the basis $\{\mathbf{e}_j\}$, the 2-form B is represented by the $n \times n$ matrix

$$\begin{pmatrix} 0 & 1 & & & & & & \\ -1 & 0 & & 0 & & & 0 & \\ & & \ddots & & & & & \\ & 0 & & 0 & 1 & & & \\ & & & -1 & 0 & & & \\ & & & & & 0 & & \\ & 0 & & & & & \ddots & \\ & & & & & & & 0 \end{pmatrix},$$

in which the lower right $(n-2) \times (n-2)$ block is zero.

It is straightforward to verify that the rank of the 2-form B is indeed $2k$ according to the definition (1.25) of the rank. The $2k$-form $B^{\wedge k}$ is nonzero due to the linear independence of $\{\theta_j\}$,

$$B^{\wedge k} = k!\,\theta_1 \wedge ... \wedge \theta_{2k},$$

while $B^{\wedge(k+1)} = 0$. ■

The difference between the algebraic and the differential-geometric versions of the Darboux theorem is the following. According to the algebraic theorem just proved, one may reduce any 2-form Ω to a canonical decomposition at any one point p. This decomposition will involve a certain choice of the 1-forms $\{\theta_j|_p\}$ at each p. However, this procedure will generally generate different sets $\{\theta_j|_p\}$ in tangent spaces at different points p, so there will be no local coordinate system $\{x_j\}$ in which the 1-forms θ_j are equal to the coordinate 1-forms $\mathrm{d}x_j$ at every point p. Using the algebraic version of the Darboux theorem, one could obtain the decomposition (1.24) at any one point p but not at neighboring points. The differential-geometric Darboux theorem says that one can actually choose a local coordinate system in which the 2-form Ω has a canonical decomposition (1.24) at every point within some domain.

* Proof of the Darboux theorem

The Darboux theorem states that a closed 2-form Ω of local rank $2k$ in a n-dimensional manifold can be written as

$$\Omega = \mathrm{d}x_1 \wedge \mathrm{d}x_2 + ... + \mathrm{d}x_{2k-1} \wedge \mathrm{d}x_{2k}$$

in a suitable local coordinate system. This theorem is proved in three steps.

The first step is to show that there exists a local coordinate system $\{x_1, ..., x_n\}$ such that Ω depends *only* on the first $2k$ coordinates $\{x_1, ..., x_{2k}\}$, i.e.

$$\Omega = \frac{1}{2}\sum_{i,j=1}^{2k} \Omega_{ij}(x_1, ..., x_{2k})\mathrm{d}x_i \wedge \mathrm{d}x_j.$$

Then it is sufficient to consider the 2-form Ω on a $2k$-dimensional submanifold where the remaining coordinates $\{x_{2k+1}, ..., x_n\}$ have fixed values.

The first step can be proved as follows. If a 2-form $\Omega \neq 0$ has rank $2k < n$ then, by Statement 1.4.7.1, at every point there exists a decomposition of the form (1.26). It follows that in the tangent space at every point p, there will exist a nonempty subspace of vectors $\mathbf{v}$ such that $\iota_\mathbf{v}\Omega = 0$. Since the 2-form Ω is smooth, this subspace will also vary smoothly between points. So at least one smooth vector field $\mathbf{v} \neq 0$ can be chosen such that $\iota_\mathbf{v}\Omega = 0$ at every point within some domain. A local coordinate system $\{x_1, ..., x_n\}$ can be chosen such that $\mathbf{v} = \partial/\partial x_n$. Then the property $\iota_\mathbf{v}\Omega = 0$ means that the expression for Ω may contain $\mathrm{d}x_1, ..., \mathrm{d}x_{n-1}$ but no $\mathrm{d}x_n$. Further, we have $\mathrm{d}\Omega = 0$ and thus (by the Cartan homotopy formula)

$$\mathcal{L}_\mathbf{v}\Omega = (\mathrm{d}\iota_\mathbf{v} + \iota_\mathbf{v}\mathrm{d})\,\Omega = 0.$$

The property $\mathcal{L}_\mathbf{v}\Omega = 0$ means that the coefficients $\Omega_{ij}(x_1, ..., x_n)$ in the decomposition (1.23) do not actually depend on the coordinate x_n (see Statement 1.3.2). Thus, it is sufficient to study the restriction of the 2-form Ω to an $(n-1)$-dimensional submanifold of constant x_n. The same construction can be applied to the reduced 2-form Ω. If the rank of Ω is smaller than $n-1$, anther coordinate x_{n-1} can be found such that Ω does not indolve $\mathrm{d}x_{n-1}$ and the coefficients Ω_{ij} do not depend on x_{n-1}. Thus we will reduce Ω to an $(n-2)$-dimensional manifold, etc. Each time, the dimension of the manifold is reduced by one, until we obtain a 2-form Ω of rank $2k$ on a $2k$-dimensional manifold, i.e. a 2-form of maximal rank. A 2-form of maximal rank is nondegenerate (Statement 1.4.7.1). Thus it is sufficient to prove the Darboux theorem only for nondegenerate 2-forms.

The second step is to prove that there exists a local coordinate system $\{x_1, ..., x_n\}$ such that a given closed, nondegenerate 2-form Ω has *constant* coefficients Ω_{ij} in the coordinates $\{x_j\}$,

$$\Omega = \frac{1}{2}\sum_{i,j=1}^{2n} \Omega_{ij}^{(0)}\mathrm{d}x_i \wedge \mathrm{d}x_j, \quad \Omega_{ij}^{(0)} = -\Omega_{ij}^{(0)} = \text{const}.$$

This involves a differential-geometric argument detailed below. The third step is to reduce the nondegenerate, antisymmetric $2n \times 2n$ matrix $\Omega_{ij}^{(0)}$ to the canonical form

$$\begin{pmatrix} 0 & 1 & & & \\ -1 & 0 & & 0 & \\ & & \ddots & & \\ & 0 & & 0 & 1 \\ & & & -1 & 0 \end{pmatrix}.$$

The reduction is performed through a change of basis. According to Statement 1.4.7.1, a basis $\{\mathbf{e}_1, ..., \mathbf{e}_{2n}\}$ can be chosen such that the matrix $\Omega_{ij}^{(0)}$ assumes the canonical form shown above (there is no zero block since $\Omega_{ij}^{(0)}$ has maximal rank).

It remains to perform the second step. We fix a point p at which

$$\Omega|_p = \frac{1}{2}\sum_{i,j=1}^{2n} \Omega_{ij}^{(0)}\mathrm{d}x_i \wedge \mathrm{d}x_j,$$

and define a new 2-form Ω_0 at all other points by the formula

$$\Omega_0 = \frac{1}{2}\sum_{i,j=1}^{2n} \Omega_{ij}^{(0)}\mathrm{d}x_i \wedge \mathrm{d}x_j.$$

By construction, $\Omega = \Omega_0$ at p, while Ω_0 has "constant coefficients" in the given coordinate system. Now we would like to find a change of coordinates in a neighborhood of p such that Ω has constant coefficients in the new coordinates. This is equivalent to finding a diffeomorphism $f : \mathcal{M} \to \mathcal{M}$ such that $f(p) = p$ and $f(\Omega) = \Omega_0$. Instead of finding f directly, we will find a one-parametric *flow* of diffeomorphisms f_t, $t \in [0, 1]$, such that $f_0 = \mathrm{id}$ (the identity map) and $f_1 = f$ is the map we need.

We would like to find a map f_t that transforms Ω into a 2-form Ω_t which is "between" Ω and Ω_0. The first trick is to write such an interpolation explicitly, i.e. we define

$$\Omega_t \equiv \Omega + t\,(\Omega_0 - \Omega)\,.$$

The 2-form $\Omega_0 - \Omega$ is closed and thus, by the Poincaré lemma, there exists a 1-form θ such that

$$\Omega_0 - \Omega = \mathrm{d}\theta$$

(perhaps, the above will hold only in a smaller star-shaped neighborhood of the initial point p). The second trick is to describe the flow f_t through a tangent vector field $\mathbf{v}_t$. The vector field $\mathbf{v}_t$ will be obtained by the duality map from the 1-form θ, using the 2-form Ω_t as the "metric." Converting a 1-form into a vector field is possible only if Ω_t is nondegenerate at every point and for every $t \in [0,1]$. We postpone the proof of the nondegeneracy of Ω_t, and presently we assume that we have a vector field $\mathbf{v}_t$ satisfying

$$\iota_{\mathbf{v}_t}\Omega_t = \theta, \quad t \in [0,1]\,.$$

We now define the flow f_t as the flow generated by the (time-dependent!) vector field $\mathbf{v}_t$. By construction, the flow f_t transforms Ω into a t-dependent 2-form $\Omega(t)$ which satisfies the differential equation

$$\frac{d}{dt}\Omega(t) = \mathcal{L}_{\mathbf{v}_t}\Omega(t).$$

It is then straightforward to verify that the interpolation Ω_t satisfies this equation:

$$\frac{d}{dt}\Omega_t = \Omega_0 - \Omega = \mathrm{d}\theta,$$
$$\mathcal{L}_{\mathbf{v}_t}\Omega_t = (\mathrm{d}\iota_{\mathbf{v}_t} + \iota\mathrm{d})\,\Omega_t = \mathrm{d}\iota_{\mathbf{v}_t}\Omega_t = \mathrm{d}\theta.$$

Thus $\Omega_t = \Omega(t)$ and is indeed the result of the transformation of the initial 2-form Ω by the flow f_t. The diffeomorphism f_1 corresponding to $t = 1$ is the one that transforms Ω into Ω_0.

It remains to demonstrate that the 2-form Ω_t has maximal rank for every $t \in [0,1]$ and at every point within some domain. We note that Ω_t interpolates between Ω and Ω_0, while the 2-forms Ω and Ω_0 coincide at the chosen point p. Since $\Omega_t = \Omega$ at p, it is clear that Ω_t at p remains nondegenerate for all t; the present task is to show that Ω_t has maximal rank everywhere in some open domain around p. The 2-form Ω_t has maximal rank $2n$ iff $\Omega_t^{\wedge n} \neq 0$. The $2n$-form $\Omega_t^{\wedge n}$ is proportional to the volume form $\mathrm{d}x_1 \wedge ... \wedge \mathrm{d}x_{2n}$, namely

$$\Omega_t^{\wedge n} = f_t(x)\,\mathrm{d}x_1 \wedge ... \wedge \mathrm{d}x_{2n},$$

where the coefficient, temporarily denoted by f_t, is a function of the coordinates $\{x_j\}$. The rank of Ω_t is maximal if $f_t(x) \neq 0$. We know that $f_t(p) \neq 0$ for every $t \in [0,1]$. Since the function f_t is smooth, the domain where $f_t \neq 0$ is a t-dependent open set containing the point p. The intersection of all such domains for every $t \in [0,1]$ is again a nonempty open set (possibly smaller than the set where Ω has maximal rank). Thus, we have found an open domain containing the initial point p where Ω_t is nondegenerate at every t.

* Canonical decomposition of 1-forms

The concepts of rank and canonical coordinates can be defined also for 1-forms. Heuristically, the rank of a 1-form is the smallest number of independent coordinates required to express this 1-form. This time, we do not limit ourselves to considering only closed 1-forms; but let us briefly examine the case of a closed 1-form. By the Poincaré lemma, a closed 1-form ω is locally represented as $\omega = \mathrm{d}f$ using some function f. The function f will be nonconstant if $\omega \neq 0$. Thus, f can be used as one of the coordinates in a local coordinate system; so ω can be expressed using just one coordinate. We conclude that a closed, nonzero 1-form has rank 1.

Below we will prove that any 1-form ω can be expressed (using suitable local coordinates) in one of two canonical ways: either

$$\omega = x_1\mathrm{d}x_2 + ... + x_{2k-1}\mathrm{d}x_{2k} \tag{1.27}$$

(then we say that ω has rank $2k$), or

$$\omega = x_1\mathrm{d}x_2 + ... + x_{2k-1}\mathrm{d}x_{2k} + \mathrm{d}x_{2k+1} \tag{1.28}$$

(then ω has rank $2k+1$). We may call the coordinates used for such decompositions **canonical coordinates** of a given 1-form.

Knowing that this statement is true, how could we determine the rank of a given 1-form ω, for example,

$$\omega = \mathrm{d}x + xy\mathrm{d}z,$$

without knowing the canonical coordinates? We use the following trick. Consider the 2-form $\mathrm{d}\omega$ and compute its exterior powers, $(\mathrm{d}\omega)^{\wedge k}$, $k = 1, 2, ...$ Write the following sequence of the differential forms,

$$\omega,\ \mathrm{d}\omega,\ \omega\wedge\mathrm{d}\omega,\ \mathrm{d}\omega\wedge\mathrm{d}\omega,\ \omega\wedge\mathrm{d}\omega\wedge\mathrm{d}\omega,\ ... \tag{1.29}$$
